The molecular biology revolution has had a profound impact on spin label ESR. The limitations of using naturally occurring binding sites are circumvented by the site-directed spin-labeling method pioneered by Hubbell et al.\(^{(30)}\). In SDSL, native cysteines are mutated out and new cysteines are introduced at desired vantage points. The power of this method is best illustrated by cysteine scanning where each residue along the polypeptide chain is changed to a cysteine and labeled with nitroxide.

Noncovalent labels are used in the investigation of active sites, e.g. substrate or cofactor analogs, adenosine triphosphate (ATP) or nicotinamide adenine dinucleotide (NAD) nitroxide adducts (Figure 3a–c). The binding and function of these substrates are often not compromised by the presence of the nitroxide. Both approaches

PEPTIDES AND PROTEINS

4 TECHNIQUES AND INSTRUMENTATION

4.1 Continuous Wave Electron Spin Resonance

4.1.1 Theory

The magnetic moment, \( \mu \), of an electron interacts with an external magnetic field just like a compass needle interacts with the earth’s magnetic field. The interaction of electron spin with the field is often referred to as the Zeeman interaction. The energy \( E \) of a magnetic dipole (\( \mu \)) in a static magnetic field is given by Equation (1):

\[
E = -\mu H
\]
where $H$ is the magnetic field strength. The magnetic moment of an electron is generated by its spin ($S$) (Equation 2):

$$\mu = -g\beta S$$  \hspace{1cm} (2)$$

with $\beta$ denoting the Bohr magneton (intrinsic unit of electron magnetic moment) and $g$ denoting the spectroscopic splitting factor (relates contribution of spin and orbital motion of the electron to its total angular momentum).

Unlike a compass needle, electron spin is quantized. For a single electron, the projection of $S$ on the magnetic field axis $S_z$ can only take values of $\pm 1/2$. Thus the energy levels from Equations (1) and (2) are $E = \pm (1/2) g\beta H$, resulting in an energy gap which increases linearly with the magnetic field, $\Delta E = g\beta H$ (Figure 4). An oscillating magnetic field can flip the electrons from one energy level to the other if its own energy, defined by the oscillating frequency $\nu$, equals the energy gap. Hence, for resonance between the oscillating field (microwave) and the electron spin, the condition in Equation (3) has to be satisfied:

$$\nu = g\beta H$$  \hspace{1cm} (3)$$

The resonance condition can also be obtained by considering a spinning electron moving in an orbit around a nucleus placed in a magnetic field. From classical mechanics, the rate of change of the magnetic moment is proportional to the torque produced by the interaction of the moment and the magnetic field and given by their vector product (Equation 4):

$$\frac{\delta\mu}{\delta t} = \mu \otimes \gamma H$$  \hspace{1cm} (4)$$

where $\gamma$ is a magnetogyric ratio (ratio of magnetic and inertia moments) characteristic of a given electron (Equation 5)

$$\gamma = \frac{g\beta}{\hbar}$$  \hspace{1cm} (5)$$

where $\hbar$ is Planck’s constant. The torque will force the magnetic dipole ($\mu$) to precess around the static field at a defined frequency, the Larmor frequency, $w$, given by Equation (6):

$$w = \gamma H$$  \hspace{1cm} (6)$$

Substitution of $\gamma$ from Equation (5) into Equation (6) yields the resonant condition $\nu = g\beta H$ stated in Equation (3). Applying an oscillating microwave field of the same frequency as the Larmor frequency cancels the orienting effect of the static magnetic field. The spin then rotates about an axis perpendicular to the static field direction, periodically aligning itself with or against the static field. This is equivalent to dipole ($\mu$) flipping between the two energy levels.

The extent of microwave absorption, which defines the intensity of the ESR signal, is proportional to the difference in spin populations, $N$, between the upper and lower energy states. The ratio of the two populations is determined by the Boltzmann distribution (Equation 7):

$$\frac{N_{\uparrow}}{N_{\downarrow}} = \exp \left( \frac{\Delta E}{kT} \right)$$  \hspace{1cm} (7)$$

The difference in spin populations is increased by either increasing the magnetic field $H$ or reducing the temperature $T$. For example, at 0.35 T and room temperature the population difference is 0.1% but it can be increased to 13% by reducing the temperature to 3 K. The difference between the levels decreases with absorption and an efficient relaxation pathway has to exist to restore the Boltzmann equilibrium. Relaxation pathways include the dipolar spin–spin relaxation – sharing of energy between electrons or nuclei – and spin–lattice relaxation – sharing vibrational modes with the lattice. They are characterized by relaxation times $T_2$ and $T_1$, respectively. Relaxation times are defined as the time interval between initial perturbation and when the deviation from equilibrium decays to $1/e$ of its initial value. The relaxation rates are additive and their sum defines the width (at half-height) of the resonance, $\Gamma$ (Equation 8):

$$\Gamma = \frac{1}{\gamma} \left( \frac{1}{T_2} + \frac{1}{T_1} \right)$$  \hspace{1cm} (8)$$

Faster relaxation (shorter $T_1$ or $T_2$) results in broader line widths. For paramagnetic ions, the strong coupling of spins to lattice (short $T_1$) produces broad lines. Lowering the temperature weakens lattice coupling (increases

![Figure 4](image-url)
magnitude of the isotropic splitting of a nucleus has both an isotropic and dipolar component. The nuclear spin interacts with the unpaired electron. For $^{15}$N, the nuclear spin number $I$ is 1/2, which means that two electron transitions are observed; for $^{14}$N, $I = 1$ and therefore there are three electron transitions. The resonance condition of Equation (3) is thus modified to include hyperfine interactions, $A$ (Equation 9):

$$\hbar v = g\beta H + m_I A$$

The hyperfine interaction between an electron and the nucleus has both an isotropic and dipolar component. The magnitude of the isotropic splitting, $a_0$, is proportional to the electron spin density on the nucleus. Since the unpaired electron is located between the oxygen and nitrogen, increasing the polarity of the medium decreases the oxygen’s attraction and increases the electron density on the nitrogen. Thus, $a_0$ is a sensitive measure of the spin environment.

The $\pi\sigma$ orbital of an unpaired electron is asymmetric, making the dipolar interactions of the electron and nucleus orientation dependent. For example, hyperfine interactions are stronger when the z-axis of the orbital is aligned with the magnetic field and weaker when the field is aligned perpendicular. The hyperfine interactions are best described by a second rank tensor, $A$ (Equation 10):

$$A = \begin{pmatrix} A_{xx} & 0 & 0 \\ 0 & A_{yy} & 0 \\ 0 & 0 & A_{zz} \end{pmatrix}$$

Typical values for nitroxide spin labels are $A_{xx} \approx A_{yy} \approx 7\, G$ and $A_{zz} \approx 35\, G$. The difference between the $x$- and $y$-components is small and often the hyperfine tensor is assumed to be axially symmetric.

The Zeeman interaction of the electron spin with the static magnetic field (Equation 1), is also anisotropic. Asymmetry of orbital motion in the $\pi\sigma$ orbital results in different contributions of spin and orbital momenta and thus the $g$-value can also be described by a tensor (Equation 11):

$$g = \begin{pmatrix} g_{xx} & 0 & 0 \\ 0 & g_{yy} & 0 \\ 0 & 0 & g_{zz} \end{pmatrix}$$

In contrast to the hyperfine tensor, the $g$ tensor is rhombic with typical values $g_{xx} \approx 2.0085$, $g_{yy} \approx 2.0065$ and $g_{zz} \approx 2.0027$. The asymmetry of the Zeeman and hyperfine interactions defines ESR sensitivity to orientation and to rotational motion.

4.1.2 Electron Spin Resonance Spectrometer

A modern ESR instrument consists of three basic units: (a) a microwave bridge and resonator, (b) a variable field magnet and (c) signal amplification circuitry (Figure 5). Microwaves of the desired frequency are generated by either a klystron or Gunn diode. Their intensity is adjusted by an attenuator and transmitted via a waveguide to the sample chamber/resonator. During resonance, a small amount of microwaves is reflected from the resonator and detected by a Shottky diode. To separate the reflected and incident microwaves, a circulator is placed between the attenuator and resonator. The circulator channels the microwaves in a forward direction: incident microwaves to the resonator and reflected microwaves to the detector. The bridge often contains an additional pathway – a reference arm which taps off a small fraction of the microwaves from the source – which bypasses the resonator and falls on to the detector to ensure its bias for the optimal detection of small intensity changes during resonance.

A static magnetic field is provided by an electromagnet stabilized by a Hall probe. The field is slowly swept by varying the amount of current passing through the electromagnet. In order to decrease microwave noise,
the resonance signal is encoded by modulating the static field with a small magnetic field generated by modulation coils. The modulation field sweeps periodically through the nitroxide resonance field. Therefore, the changes in microwave absorption due to resonance occur with the modulation frequency. A lock-in amplifier selects and amplifies only the signal which is in phase and in frequency with the modulation field and rejects all other microwave fluctuations as noise. The signal detected using field modulation is proportional to the changes in the microwave intensity during one cycle of modulation, i.e. the signal is the first derivative of the absorption (Figure 6a–b).

The microwave field produced by the klystron is too weak to induce any detectable absorption by the sample. Resonant cavities, loop gap resonators (LGRs) or, more recently, dielectric resonators (DRs) are used to increase the microwave magnetic field at the sample. The cavities rely on the generation of a standing wave pattern of microwaves whose intensity builds up during cavity resonance. The main drawback of cavities is the presence of an electric component of the microwave. The electric component is absorbed by “lossy”, aqueous samples (common in biology) causing sample heating and loss of cavity resonance. To avoid this problem, sample volume is restricted to the nodal planes of the electric field, limiting the usable volume of the cavity and thus resulting in a low filling factor, \( \eta \). Cavities are high-\( Q \) structures \( (Q = E_{\text{stored}}/E_{\text{dissipated}}) \), storing thousands of times more energy than is dissipated on the walls. High \( Q \) can only be achieved within a narrow frequency bandwidth of stored microwaves as \( Q = \nu / \Delta \nu \). Small changes in the sample, cavity geometry or temperature can all cause frequency shifts and mismatching of the incident microwave with the cavity. Automatic frequency control (AFC) circuitry is employed to track the frequency of the klystron to that of the cavity. However, the AFC feedback response time limits the deadtime of signal changes in transient experiments such as stop-flow. In pulse experiments it is necessary to wait until the energy of the perturbing pulse is fully dissipated. This ring-downtime is proportional to \( Q \); thus in the high-\( Q \) structures a longer time has to elapse before a relatively weak spin echo or free induction decay (FID) signal can be collected.

Most of these problems with cavities have been overcome by low-\( Q \) resonators such as an LGR or DR. These resonators condense the magnetic component of the microwave, separating it from the electric component. Lossy samples are no longer heated by the electric component. Small sample volumes and large filling factors offer an additional advantage especially when dealing with genetically engineered proteins which are often purified in picomolar quantities. Furthermore, fast dissipation of energy and the large bandwidths of LGRs and DRs make them suitable for pulsed and transient experiments.

4.1.3 Instrumental Variables Affecting the Electron Spin Resonance Spectrum

Two instrumental parameters influence the line shape of experimental spectra: modulation amplitude and microwave power. The amplitude of the ESR signal initially increases with the modulation amplitude \((H_m)\) as it approaches the intrinsic line width \((\Delta H_{pp})\). Maximum amplitude is attained at \(H_m = 3.5\Delta H_{pp}\) for Lorentzian and at \(H_m = 1.8\Delta H_{pp}\) for Gaussian line shapes. Any further increases in \(H_m\) result in a decrease of the signal. The broadening of \(\Delta H_{pp}\) is observed well before the maximum amplitude of the signal. When \(H_m = \Delta H_{pp}\), the observed Lorentzian and Gaussian widths are 25% and 15% larger, respectively. As a rule of thumb, modulation should be kept at one-fifth of the intrinsic line width when resolution or line width is of importance. The errors in line width are then \(<1\%\).

The ESR signal is proportional to the static microwave field, \(H_1\), and hence to the square root of the microwave power \( (P^{1/2})\), in the absence of saturation. When the rate of relaxation lags behind the rate of excitation and when the spin populations in the ground and excited states are equalized, the signal saturates and decreases to nil. The amplitude of the ESR signal \((y)\) for a Lorentzian line shape as a function of the microwave field is given by

**Figure 6** Conventional ESR signals: (a) absorption, \(V_0\); (b) first derivative \(V_1\); (c) STESR spectrum, second derivative, 90° out-of-phase display, \(V_2\).
where $y_0$ is a field-independent parameter. Hence it is important to keep power levels well below the maximum amplitude whenever spectra are used to quantify the number of spins. Line-width distortions are less pronounced than those due to the modulation field, but at powers giving maximum amplitude, the observed line width increases 1.2 times over the intrinsic line width.

### 4.2 Saturation Transfer Electron Spin Resonance

#### 4.2.1 Qualitative Theory

STESR was developed to study slower molecular dynamics with rotational correlation times ($\tau_1$) of $>200$ ns. The timescale of conventional ESR is determined by the spin–spin relaxation time $T_2$ (nanoseconds). The ESR timescale can be extended to a longer spin–lattice relaxation time $T_1$ (microseconds) if a signal sensitive to spin saturation is observed. This can be done by saturating the signal with intense microwaves, creating a “hole” in the absorption spectrum, and subsequently observing signal recovery. When the saturating microwave is switched off (or decreased to nonsaturating levels) the signal recovers with the rate determined by the spin–lattice relaxation time, $T_1$. The onset of motion provides an additional relaxation mechanism: spectral diffusion. The saturation is relieved as the resonating-saturated spins rotate away from the resonance field and the unsaturated spins come into resonance. The “hole” broadens out across the spectrum and the intensity of the signal increases. The second harmonic, out-of-phase ESR signal ($V_2$), collected at moderate saturation, is particularly sensitive to spectral diffusion. The line shape of $V_2$, in the presence of saturation, bears a strong resemblance to the absorption spectrum with the intensity lowered in the spectral regions most sensitive to the spectral diffusion (see Figure 6c).

#### 4.2.2 Instrumental Parameters

The STESR signal is influenced by nitroxide relaxation times, spectral diffusion, spin saturation level and the modulation frequency with which the “hole” is observed. Hence the instrumental parameters which affect any of these must be precisely controlled. The saturating microwave field averaged over the sample volume is set to 0.25 G. The microwave power is adjusted to this level using the microwave field conversion factor ($c$), corrected for a filling factor ($n$) and dielectric losses, which lower the $Q$ factor (Equation 13): 

$$\langle H_E^2 \rangle_{1s} = cPQ$$

where $P$ is incident microwave power. The power-to-field conversion factor is determined experimentally by the saturation of Frenzy salt [peroxylamine disulfonate (PADS)] for which the half-saturation field is 0.1067 G.

The modulation frequency and amplitude, which determine the frequency of the stepping on- and off-resonance, i.e. the interval between burning and observing the “hole”, must also be calibrated. Modulation broadening of a narrow line-width sample, e.g. Frenzy salt, is used for this purpose. The observed line width ($\Delta H_{pp}$) is dominated by modulation broadening when the modulation amplitude is $\sim$10 times the intrinsic line width [$\Delta H_{pp}(0)$], i.e. $\Delta H_{pp} = H_m - \Delta H_{pp}(0)$. Commonly used values for the modulation field are 5 G and 50 kHz.

Finally, since the $V_2$ STESR signal is $90^\circ$ out of phase (phase quadrature) with modulation, the precise phase nil must be found. An error of 1° in setting the phase quadrature can result in significant line-shape changes due to leakage of a more intense in-phase signal. The most popular phase nulling method is by interpolation of the unsaturated in-phase signal: two or three readings are taken within $15^\circ$ on each side of the putative nil and the phase at which the signal is zero is found by linear interpolation. A general description of the experimental procedures and calibration can be found in Fajer and Marsh and Squier and Thomas. Digital post-acquisition methods have also been proposed but are not widely used.

As a footnote, protein mobilities measured by conventional ESR and STESR were independently verified by optical methods – fluorescence and phosphorescence anisotropy. Bovine serum albumin labeled with a dual probe bearing a spin label moiety and the optical probe eosin was measured using optical methods and ESR/STESR. The agreement between the fluorescence/phosphorescence and ESR was excellent.

### 4.3 Time Domain Methods

Time domain ESR relies on the perturbation of the equilibrium magnetization by an intense microwave pulse which is then followed by one of the following: (a) conventional ESR to observe the return of magnetization to equilibrium – saturation recovery ESR; (b) refocusing of the magnetization in the $xy$-plane – spin-echo ESR; or (c) free induction decay (FID) of the magnetization in the $xy$-plane which is then Fourier transformed (FTESR).

The development of time domain ESR posed a formidable technical challenge. The microwave pulse must be short (a few nanoseconds) and strong enough to
cover a 70-G wide spectrum of nitroxides. The resonators must dissipate the pulse energy within tens of nanoseconds before the loss of magnetization coherence and the signal must be digitized with a subnanosecond dwell time owing to the short nitroxide relaxation times. Fortunately, technological advances in microwave sources, resonator design and data acquisition electronics in the last decade have facilitated development of commercial Fourier transform spectrometers and the time domain method has become increasingly popular. The various time domain ESR techniques are illustrated in Figure 7(a–c).

Saturation recovery electron spin resonance (SRESR) is a hybrid of continuous wave and pulse methods in which the pulse saturates a spin population at a desired field thereby creating a “hole” in the absorption spectrum (Figure 7a). The kinetics of recovery are determined by various relaxation pathways: spin–lattice relaxation, nuclear relaxation, Heisenberg spin exchange (HSE) or spectral diffusion. These competing pathways can be resolved by varying the pulse duration. SRESR has been used successfully in the determination of spin–lattice correlation times and spin exchange.

Spin-echo electron spin resonance (SEESR) uses a sequence of pulses; in Hahn echo a 90° pulse is followed by a 180° pulse \( t_1 \) seconds later (Figure 7b). The first pulse tips the magnetization into the \( xy \)-plane where individual spins rotate with their respective Larmor frequency, \( w \). The difference in Larmor frequencies, which arises from different resonant fields, leads to dephasing of the magnetization in the \( xy \)-plane which is then refocused by the 180° pulse. Spins lagging by \( \Delta w t_1 \) before the refocusing pulse are now \( \Delta w t_1 \) ahead.

At time \( 2t_1 \), spins are brought into coherence and an echo is formed. In this way static differences in Larmor frequency due to different resonant fields or different local fields (inhomogeneous broadening) are annihilated. The dependence of the echo amplitude on time \( t_1 \) reveals Larmor frequency fluctuations that cannot be refocused by the 180° pulse. These fluctuations contain information about molecular dynamics, spin exchange and dipolar interactions. The decrease of the spin echo as a function of \( t_1 \) is a measure of the \( T_2 \) relaxation time. The decay of the echo amplitude is often recorded as a function of spectral position by stepping the magnetic field, resulting in a 2-D spectrum: an inhomogeneously broadened spectrum along the field axis and a homogeneous line shape on the \( t_1 \) axis. Since the inhomogeneous broadening often obscures a multitude of phenomena affecting ESR line width, then the ability to obtain a pure, homogeneously broadened spectrum is of considerable value.

2-D FTESR is the most versatile technique of time domain ESR (Figure 7c). All the spins are excited simultaneously with a strong, short microwave pulse which tips the magnetization into the \( xy \)-plane. The length and strength of the signal determine the spectral range covered, e.g. for nitroxides with a 200-MHz spectral range, 2-kW pulses 5 ns in duration are needed.

Coherently excited spins precess about a magnetic field at their Larmor frequency. This precession can be detected as an oscillating signal in the \( xy \)-plane which decays in time as the spins lose coherence. This FID signal is Fourier transformed into the frequency domain to yield an absorption spectrum. Application of two or more pulses spaced by varying intervals allows sampling of spin coherences in multiple dimensions. In the simplest of these experiments, two-pulse spin-echo correlation spectroscopy (SECSY), the first pulse tips the magnetization into the \( xy \)-plane where the spins become frequency labeled during the evolution time \( t_1 \). A second pulse reverses the magnetization during the collection time \( t_2 \), canceling inhomogeneous broadening. Fourier transformation with respect to \( t_1 \) and \( t_2 \) yields an absorption spectrum along the \( f_2 \) axis and a homogeneous line width along the \( f_1 \) axis. Thus SECSY is an FTESR equivalent of field-stepped SEESR. The isolation of the homogeneous line shapes out of an inhomogeneously broadened spectrum is used to study molecular dynamics.

Three pulse sequences are used in 2-D ELDOR experiments (e.g. Figure 7c). The first pulse creates a transverse magnetization in the \( xy \)-plane which evolves for time \( t_1 \). The second pulse stores this frequency encoded magnetization along the \( z \)-axis allowing for

---

**Figure 7** Time domain ESR methods: (a) saturation recovery; (b) spin echo; (c) 2-D FTESR (ELDOR).
magnetization transfer to take place during mixing time $T_M$. A third pulse transforms the magnetization back into the $xy$-plane where it is observed during time $t_2$. Magnetization transfer changes the resonant frequency of a spin from $f_1$ to $f_2$, creating an off-diagonal cross peak at $(f_1, f_2)$ (Figure 8). The time evolution of the amplitude of the cross peak, measured by varying $T_M$, is used to determine the time course of magnetization transfer. The biophysically relevant phenomena causing magnetization transfer include HSE, modulation of dipolar interactions, nuclear flips and, most importantly, spectral diffusion due to rotational motion.

5 APPLICATIONS OF SPIN LABELING

The orientational difference of magnetic interactions (referred to anisotropy) forms the basis of spin labeling techniques in biological research. In the absence of motion, each field position corresponds to a defined orientation of the label with respect to the field. The intensity of the signal at a particular field position is directly proportional to the population of molecules with that given orientation. Hence an ESR spectrum can be used to determine the range of orientations present in a sample. Partially or fully averaging the $g$- and hyperfine tensor anisotropy results in spectral line shapes determined by the frequency and amplitude of molecular motion. ESR can also be used to measure intra- and intermolecular distances. The presence of paramagnetic centers in the vicinity of spin labels modulates spin relaxation pathways in a distance-dependent manner. In this section we shall discuss how ESR is used in the investigation of molecular orientation, molecular dynamics, ligand binding, intra- and intermolecular distance measurements and the determination of various levels of protein structure.

For each of these applications a qualitative description of the physical principles allowing for these measurements will be given, followed by examples. More extensive reviews of these topics can be found in a monograph by Lichtenstein,38 a series edited by Berliner and Reuben39,40 and separate reviews by Hubbell et al.,41–43 Marsh and Horvath,44 Millhauser et al.,45,46 and, most recently, Hustedt and Beth.47

5.1 Protein Orientation

5.1.1 Orientation of a Single Molecule

The anisotropy of the Zeeman and hyperfine interactions confers orientational sensitivity to ESR spectra. Nitroxide spin labels with a $z$-axis parallel to the magnetic field generate a spectrum with a splitting of 70 G. Spins oriented perpendicular to the field display a splitting of 14 G (Figure 9).

The center position of the spectrum, determined by the $g$-tensor, is sensitive not only to the position of the $z$-axis but also to the orientation of the $x$- and $y$-axes. At 9 GHz the center is shifted 5 G downfield (left) for a spin with its $y$-axis aligned with the magnetic field and another 4 G for spins with $x$-axis parallel to $H_0$ (Figure 9).

The effective $g$- and hyperfine splitting tensors for a spin placed at an arbitrary polar angle $(\theta, \phi)$ with respect to the field are given by Equations (14) and (15), respectively:

$$g(\theta, \phi) = g_{xx} \sin^2 \theta \cos^2 \phi + g_{yy} \sin^2 \theta \sin^2 \phi + g_{zz} \cos^2 \theta$$

\[ (14) \]
ESR LABELING IN PEPTIDE AND PROTEIN ANALYSIS

\[
A^2(\theta, \phi) = A_{zz}^2 \sin^2 \theta \cos^2 \phi + A_{yy}^2 \sin^2 \theta \sin^2 \phi + A_{zz}^2 \cos^2 \theta
\]  

It follows, then, that the resonance field for a given orientation \((\theta, \phi)\) is given by Equation (16):

\[
H_{\text{res}}(\theta, \phi, m) = \frac{h}{g(\theta, \phi)} + m_i A(\theta, \phi)
\]  

Equation (16) describes the orientational resolution of ESR line shapes: a spin with a specific orientation can be found at a defined position along the field axis. The ESR intensity at any field position is directly proportional to the number of spins at the orientation defining \(H_{\text{res}}\). An ESR spectrum can also be considered as an orientational distribution function, \(N(\theta), N(\phi)\) is approximated by an orthonormal set of spherical harmonics and has been developed and applied to samples with cylindrical and planar symmetry.\(^4\)\(^8\)\(^9\)

Alternatively, the orientation can be modeled in terms of a Gaussian distribution with a width \(\Delta \theta\) and center \(\theta_0\) (Equation 17):

\[
\rho(\theta) = \exp \left(-\ln 2 \frac{(\theta - \theta_0)^2}{\Delta \theta^2}\right)
\]

The ESR spectrum, \(Y(H)\), is created by calculating a resonance field \(H_{\text{res}}\) for every \(\theta\) within the Gaussian distribution of orientations and placing a Lorentzian first derivative line width at \(H_{\text{res}}\) with the intensity weighted by \(\rho(\theta)\) (Equation 18):

\[
Y(H) = \rho(\theta) \frac{(H - H_{\text{res}}) \Delta H_{pp}}{(H - H_{\text{res}})^2 + \Delta H_{pp}^2}
\]

where the peak-to-peak width of the Lorentzian (\(\Delta H_{pp}\)) is defined by the spin–spin relaxation time, \(T_2\) (Equation 19):

\[
\Delta H_{pp} = \frac{2}{\sqrt{3} \gamma T_2}
\]

ESR is one of the very few biophysical techniques directly sensitive to orientational disorder. The spectra in Figure 10(a–c) illustrate this sensitivity. As the width of the Gaussian distribution increases, the ESR resonances broaden to a powder pattern limit which is characteristic of isotropically disordered spins.

In summary, the parameters describing orientational distribution (axial, azimuthal angles and their disorder) can be obtained from spectral parameters: spectral splitting, center of the spectrum and the line width respectively. This can be achieved either by graphical methods or from the automated fitting of full spectral line-shape parameters. Graphical methods compare the effective splitting and width of the resonance to graphs obtained from computer simulations. The automated method allows modeling of more complex bimodal distributions, in both \(\theta\) and \(\phi\), and can be linked to standard fitting routines such as Levenberg–Marquardt\(^{50}\) or Simplex.\(^{51}\)

5.1.2 Macromolecular Assemblies

Of considerable interest is the orientation of molecules within macromolecular assemblies, e.g. proteins within lipid membranes or contractile proteins in the muscle
fibers. If the assembly of proteins is ordered and oriented at a specific angle with respect to the magnetic field, the orientational distribution of the labeled components of the assembly can be easily determined. The spectra of such samples oriented with the symmetry axis parallel to the field are the same as for a single spin (Equation 18). When the orientation of the spin label with respect to the protein is known, the ESR spectra are interpreted in terms of the orientation of the labeled domain with respect to the assembly which is of biological interest. This is achieved using Eulerian transformations between three frames: (a) molecular frame (defining orientation of the label within the protein), sample frame (orientation of proteins within the assembly) and laboratory frame (orientation of the sample in the magnetic field) (Figure 11a and b).

The ESR spectra are simulated taking into account the orientational distribution in each of the frames. The magnetic tensors are rotated from molecular to laboratory axes using directional cosine matrices \( L \) according to Equation (20):

\[
A_{lab} = L_{mol}^T L_{sam}^T L_{lab} A_{NO} L_{lab} L_{sam} L_{mol}
\]

where \( L_{mol}, L_{sam} \) and \( L_{lab} \) are cosine matrices defined in Equation (21) for each of the Eulerian transformations and \( L^T \) is their transpose:

\[
L = \begin{pmatrix}
\cos \beta \cos \alpha \cos \gamma & -\sin \beta \sin \alpha \cos \gamma & \sin \beta \cos \gamma \\
\sin \beta \sin \gamma & \cos \alpha \sin \gamma & -\sin \alpha \sin \gamma \\
-\sin \alpha \cos \gamma & +\cos \alpha \cos \gamma & \cos \beta
\end{pmatrix}
\]

(21)

The resonant field for each spin packet is calculated as shown in Equation (22):

\[
H_{res} = \frac{h v}{p g \gamma} + m_i \sqrt{A_{zz}^2 + A_{yz}^2 + A_{zx}^2}
\]

(22)

Note that the subscripts of the \( g \)- and hyperfine tensors in Equation (22) denote elements in the laboratory frame.

5.1.2.1 Protein Orientation in Membranes The Eulerian transformation approach was introduced by Griffith et al. to determine lipid orientation in membrane bilayers. The orientation of the spin label nitroxide with respect to the lipid molecule is well defined. A stack of lipid membranes is tilted with respect to the magnetic field at a known angle, and the spectra can be defined solely by the orientational distribution in the sample frame of reference \( (\Omega_{sample}) \). The resonant field for each spin packet is calculated as shown in Equation (22):

\[
H_{res} = \frac{h v}{p g \gamma} + m_i \sqrt{A_{zz}^2 + A_{yz}^2 + A_{zx}^2}
\]

(22)

Note that the subscripts of the \( g \)- and hyperfine tensors in Equation (22) denote elements in the laboratory frame.

Note that the subscripts of the \( g \)- and hyperfine tensors in Equation (22) denote elements in the laboratory frame.
erythrocyte anion transporter, Band 3, was determined by flowing red blood cells into thin, flat, sample cells. The flow shear oriented the red blood cells parallel to the flow and the sample cell was rotated both parallel and perpendicular to the field in order to vary $\Omega_{lab}$. A global analysis of the tilt series resulted in a full description of the label orientation with respect to the normal membrane axis. The derived spin label orientation was found to be consistent with orientation results determined independently by analyzing the anisotropy of motion.

### 5.1.2.2 Muscle Proteins

Similar approaches have been used to describe the orientation of various muscle proteins. Force generation in muscle is believed to be brought about by the reorientation of the myosin cross bridges. Since ESR is sensitive to the orientation of the proteins, muscle field proved to be a fertile ground for ESR applications. Muscle fibers form a naturally ordered assembly with the fiber axis defining the cylindrical symmetry required for ESR. Proteins can be labeled directly in muscle cells or labeled as isolated components and exchanged for corresponding unlabeled proteins in the muscle sample. These include most of the thin filament proteins—actin, troponin C (TnC), troponin I (TnI) and tropomyosin—and also the thick filament components—myosin heavy chain, regulatory light chain and essential light chain. The orientation of many of these components has been extensively studied as a function of the intermediate states of the acto-myosin cycle and also during muscle activation. Thomas and Cooke have established that in the absence of ATP, myosin heads attach themselves strongly and stereospecifically to actin. Muscle relaxation, in the presence of ATP, produced disorder consistent with head detachment and Brownian motion. Subsequent studies using various nucleotide analogs to trap the intermediate adenosine triphosphatase (ATPase) states have revealed a sequence of orientational changes of the catalytic domain: a nonstereospecific attachment of transient, weakly bound heads followed by an equally large orientational disorder of the strongly attached heads in the prepower stroke state. Force generation was associated with the disorder-to-order transition. The postpower stroke state, with the hydrolysis product adenosine diphosphate (ADP) in the active site, showed a local domain heterogeneity, but overall the catalytic domain was well oriented, $\Delta\theta \pm 8^\circ$ (Figure 12). Release of ADP (rigor state) resulted in a slight change in the twist and the tilt angle of the heads. During isometric contraction, when most of the myosin heads should be in the prepower stroke state (immediately prior to the rate-limiting step of the cycle), no species were observed at a different angle to that of the postpower stroke heads. These findings excluded a simple model in which the catalytic domain (accounting for most of the myosin head mass) generates a force while rotating by $45^\circ$ from one well-defined angle to another.

A different story emerged when the labels were placed in the regulatory domain of the myosin head. Two distinct populations, centered $36^\circ$ apart, were observed in contraction (predominantly prepower stroke heads), whereas in rigor, only one population was observed. Clearly, the rotation of the head is limited to the regulatory domain with the catalytic domain shifting from a disordered to ordered structure.

The disorder-to-order transition was also found for other muscle proteins. For example, spin-labeled TnC is well ordered prior to $Ca^{2+}$ activation but becomes disordered in the presence of $Ca^{2+}$ or activating myosin heads. The loss of stereospecific, protein–protein interactions is reflected by changes to the conformational homogeneity and is the basis of many molecular mechanisms. ESR, with its capacity to see directly both the heterogeneity and anisotropy of motion, complements more popular methods such as X-ray crystallography or electron microscopy image reconstructions which ignore disorder.

### 5.2 Protein Dynamics

#### 5.2.1 Sensitivity of Conventional Electron Spin Resonance

Conventional ESR is used to study molecular dynamics on the nanosecond timescale. This timescale corresponds to motions of peptides and small proteins, or the mobility of labels on the surface of large proteins. Sensitivity of the ESR signal to motion arises from rotational modulation of the magnetic tensor anisotropy. The anisotropy...
of Zeeman or hyperfine interactions results in different resonant fields for different spin orientations. Therefore, rotational motions which change the spin label orientation will modulate the ESR line shape. This can be explained by using a two-site exchange example: two spins, A and B, resonate with frequencies \( w_A \) and \( w_B \) and exchange their positions at a rate \( 1/\tau_{ex} \). When the exchange rate is significantly slower than the difference in resonant frequencies \( (1/\tau_{ex} \gg \Delta w_{AB} = w_A - w_B) \), slow exchange), the spectrum consists of resonances A and B centered at \( w_A \) and \( w_B \), respectively, and the line widths are determined by \( T_2 \) (Figure 13). The effective relaxation rate \( 1/T_2^{eff} \) is the sum of the intrinsic \( 1/T_2 \) rate and the exchange rate \( 1/\tau_{ex} \). When the exchange frequency increases, the line widths start to broaden. Further increase of the exchange rate causes partial averaging of the resonance positions. The observed difference in resonant frequencies is reduced according to Equation (23):

\[
\Delta w_{AB} = \Delta w_{AB}^0 \left( 1 - \frac{8}{\tau_{ex}^2 \Delta w_{AB}^0} \right)
\]  

(23)

For exchange rates faster than the difference in resonant frequencies \( (1/\tau_{ex} < \Delta w_{AB}) \), fast exchange), the two resonant peaks coalesce into one peak at the average frequency (assuming equal populations of A and B) (Figure 13). The line width is determined by the effective relaxation time, \( T_2^{eff} \), with contributions from \( T_2 \) of species A and B and the exchange broadening (Equation 24):

\[
\frac{1}{T_2^{eff}} = \frac{1}{T_{2A}} + \frac{1}{T_{2B}} + \Delta w_{AB}^2 \tau_{ex} / 8
\]  

(24)

In other words, at the fast exchange limit \( (1/\tau_{ex} \gg \Delta w_{AB}) \), the contribution of the exchange rate to line width disappears and the spectrum consists of a single peak at \( 1/(2(w_A + w_B)) \) with an average line width of \( 1/T_{2A} + 1/T_{2B} \) (Figure 13).

The above considerations generally hold true for any spins exchanging between different environments such as different local magnetic fields, dipolar interactions or association with different macromolecular assemblies. Spin label reorientation with respect to the magnetic field is also a form of exchange where the rotational correlation time \( \tau_r \) is the exchange rate and the anisotropy of the \( g \)- and hyperfine interactions defines the frequency difference. At X-band, \( \Delta w = (A_{zz} - A_{xx})/h = 500 \text{MHz} \) or \( (g_{ex} - g_{zz})\hbar H/h = 185 \text{MHz} \).

As for the two-site exchange discussed above, various motional regimes of ESR can be defined: fast \( (\tau_r \approx 10^{-11} - 10^{-9} \text{ s}) \), slow \( (\tau_r \approx 10^{-8} - 2 \times 10^{-7} \text{ s}) \) and very slow \( (\tau_r > 2 \times 10^{-7} \text{ s}) \). Fast and slow motion are of the order of \( T_2 \) (15–30 ns) for electron spin and have visible effects on conventional ESR spectra which measure the transverse component of magnetization. The very slow motions do not affect transverse magnetization, but they do affect longitudinal magnetization which decays with \( T_1 \) (1–15 \text{ s})

5.2.1.1 Fast Motion \( (\tau_r \approx 10^{-11} - 10^{-9} \text{ s}) \) In the fast motional regime, the motion completely averages the anisotropy of the \( g \)- and hyperfine tensors. The rotational rate is obtained from the line width broadening using Redfield’s perturbation theory.\(^{59}\) The broadening itself is a function of the nuclear quantum spin number as different nuclear manifolds have varying anisotropy values (Equation 25):

\[
\Delta H(m_1) = A + Bm_1 + Cm_1^2
\]  

(25)

The coefficient \( A \) is equal to homogeneous broadening and coefficients \( B \) and \( C \) assure differential broadening of lines belonging to different nuclear manifolds. These coefficients are obtained from the line widths of the Lorentzian lines according to Equations (26) and (27):

\[
B = \frac{\sqrt{3}}{4} \Delta H(0) \left\{ \frac{V(0)}{V(1)} - \frac{V(0)}{V(-1)} \right\}
\]  

(26)

\[
C = \frac{\sqrt{3}}{4} \Delta H(0) \left\{ \frac{V(0)}{V(1)} + \frac{V(0)}{V(-1)} - 2 \right\}
\]  

(27)

where \( V(m_1) \) is the peak-to-peak height of a given nuclear manifold resonance and \( \Delta H(0) \) is the peak-to-peak line width of the central line.
Factors $B$ and $C$ are equal for isotropic motion and $\tau_{t}^{iso}$ is calculated directly from Equations (28) and (29):

$$\tau_{B}^{iso} = -1.22 \times 10^{-9} B$$  \hspace{1cm} (28)$$

$$\tau_{C}^{iso} = 1.19 \times 10^{-9} C$$  \hspace{1cm} (29)$$

where $B$ and $C$ are expressed in gauss and $\tau$ in seconds.\(^{61}\)

In the case of anisotropic motion, $B \neq C$, and the rates of rotation about the nitroxide $z$-, $x$- and $y$-axes are different. The ratio of $C$ and $B$ can be used to define the anisotropy as the coefficients are independent of the rate of motion. Various models of anisotropic motion are considered in excellent reviews by Marsh\(^{61}\) and Beth and Robinson.\(^{67}\) If the molecule is diffusing in an isotropic medium, then the rotational correlation times about the nitroxide $z$-axis ($\tau_{z}$) and about an axis perpendicular to the $z$($\tau_{\perp}$) are given by Equations (30) and (31):

$$\tau_{||} = \frac{2\tau_{0}\tau_{22}}{3\tau_{20} - \tau_{22}}$$  \hspace{1cm} (30)$$

$$\tau_{\perp} = \tau_{20}$$  \hspace{1cm} (31)$$

where $\tau_{0}$ and $\tau_{22}$ describe spin relaxation and are related to the anisotropy of the magnetic interactions (Equations 32 and 33):

$$\tau_{20} = \frac{1.11 \times 10^{-7} 5(\delta A)B - 8(\delta g)HC}{6\Delta A - 8\delta g\Delta A + 3(\delta g)^{2}A}$$  \hspace{1cm} (32)$$

$$\tau_{22} = \frac{3.69 \times 10^{-8} 8\delta gHC - 5\Delta AB}{6\delta A - 8\delta g\Delta A + 3(\delta g)^{2}A}$$  \hspace{1cm} (33)$$

where $\Delta A$ and $\delta A$ are given by hyperfine anisotropy (Equations 34 and 35):

$$\Delta A = A_{zz} - \frac{1}{2}(A_{xx} + A_{yy})$$  \hspace{1cm} (34)$$

$$\delta A = \frac{1}{2}(A_{xx} - A_{yy})$$  \hspace{1cm} (35)$$

with equivalent equations for $g$-anisotropy. The indices in Equations (34) and (35) are permuted to calculate the values of $\tau_{||}$ and $\tau_{\perp}$ for the rotation about the $x$- and $y$-axes of the nitroxide.

The above equations hold for anisotropic motion about a specific nitroxide axis in an isotropic medium. An additional complication arises when diffusion takes place within a strongly orientating potential such as in a lipid membrane, or within the steric confines of a protein. The field position of resonances now depends on the amplitude of motion, which defines the time average of available angular space; e.g. if the nitroxide can move only within an angular cone, then only the resonances corresponding to the orientations within the cone are averaged. Motionally averaged spectra are described in terms of order parameters ($S$) – time averages of the direction cosines of the diffusion axis with respect to the local director axis. For an isotropic diffusion within the cone angle $\theta_{c}$, components of an ordering tensor are given by Equations (36) and (37):

$$S_{zz} = \frac{1}{2}(\cos^{2}\theta_{c} + \cos\theta_{c})$$  \hspace{1cm} (36)$$

$$S_{xx} = S_{yy} = -\frac{1}{2}S_{zz}$$  \hspace{1cm} (37)$$

$S_{zz}$ and $S_{xx}$ are used to define the motionally averaged magnetic $g$-tensors $g_{||}$ and $g_{\perp}$ in terms of its average value $g_{0}$ and the anisotropy $\Delta g$ and $\delta g$ (Equations 38 and 39):

$$g_{||} = g_{0} + \frac{2}{3}\Delta gS_{zz} + \frac{1}{2}\delta g(S_{xx} - S_{yy})$$  \hspace{1cm} (38)$$

$$g_{\perp} = g_{0} - \frac{1}{3}\Delta gS_{zz} - \frac{1}{3}\delta g(S_{xx} - S_{yy})$$  \hspace{1cm} (39)$$

with equivalent expressions for the effective hyperfine splitting $A_{||}$ and $A_{\perp}$. The latter two are resolved in the experimental line shapes; see Figure 14. Thus $S_{zz}$ of the nitroxide $z$-axis can be easily obtained from Equations (38) and (39) and the corresponding cone angle from Equation (36).

5.2.1.2 Slow Motion ($\tau_{t} \approx 10^{-9} - 2 \times 10^{-7}$ s) For $\tau_{t} > 2$ ns, Redfield’s theory does not hold. The equation of motion for an electron spin is solved using a stochastic Liouville equation (SLE), developed by Schneider and Freed.\(^{60}\) Although the description of the SLE approach is beyond the scope of this article, one can rationalize the effect of slow motion on ESR spectra in terms of the two-site exchange. The low- and high-field extremes of the powder spectra correspond to nitroxides lying with the $z$-axis parallel to the magnetic field. Rotation (i.e. exchange with any other orientation) results first in an exchange broadening of the line width and then partial averaging of the anisotropy. Line width and effective splitting are

\[Figure 14 Definition of the parallel and perpendicular hyperfine splitting for calculation of order parameters.\]
used to determine $\tau_r$ (Equations 40 and 41):

$$\tau_r = a_m \left( \frac{\Delta H_m}{\Delta H^m_{0} - 1} \right)^{b_m}$$

$$\tau_r = a \left( 1 - \frac{\Delta H^m}{\Delta H^z} \right)^b$$

where $\Delta H_m$ and $\Delta H^z$ are the line widths at half-height and hyperfine splitting, respectively, and the superscripts denote their rigid limit values. Coefficients $a_m', b_m$, $a$ and $b$ are calculated from SLE simulations. Their precise values depend on the motional model used for the simulations. For a Lorentzian line width $\delta = 3.0\, \text{G}$ and isotropic Brownian diffusion, $a_{m=1} = 11.5\, \text{ns}$, $b_{m=1} = -0.943$, $a_{m=2} = 21.2\, \text{ns}$, $b_{m=2} = -0.778$, $a = 0.54\, \text{ns}$ and $b = -1.36$. Values for different line widths or motional models can be found in Marsh.$^{(61)}$

It should be noted that the calculated $\tau_r$ values depend strongly on the chosen rigid limit values. A user-friendly simulation and optimization program based on the SLE was developed by Budil et al.$^{(50)}$ Sensitivities of the conventional ESR and STESR spectra are illustrated in Figure 15(a) and (b).

**Examples.** Side-chain and polypeptide backbone dynamics are determined using the above formalism. Spin labels attached to the surface of small $\alpha$-helical peptides exhibit subnanosecond motions observed by ESR which compare well with motions predicted by molecular dynamics simulation programs.$^{(45,62)}$ Scanning of the label position along a peptide length reveals a $V$-shaped gradient of the label mobility. The cone angle for random motion in the middle of the peptide was half the value found at either terminus. Interestingly, the C-terminus was found to be more flexible than the N-terminus, which explains the decreased stability of the C-terminus as compared with the N-terminus in $\alpha$-helices.$^{(45,46)}$ Backbone dynamics observed in isolated peptides are further modulated by tertiary interactions. A survey of 30 cysteine mutants of T4 lysozyme with spin labels at various structural sites (on the surface of helices, within the helix termini, interhelical loops, buried sites and sites involved in tertiary contacts) revealed a characteristic pattern of spin label mobility in relation to the secondary structure of the protein.$^{(31)}$ When the second moment of the spectrum (defined as the reciprocal

![Figure 16](image-url)  
**Figure 16** Reciprocal of the square of the splitting versus reciprocal of the central resonance line width. The spectral parameters cluster according to the labeled protein structural elements.$^{(31)}$ [Reprinted with permission from H.S. McHaourab, M.A. Lietzow, K. Hideg, W.L. Hubbell, *Biochemistry,* 35, 7692–7704 (1996). Copyright 1996 American Chemical Society.]
of maximum splitting squared) is plotted against the reciprocal of the central field line width ($\Delta H_{\text{res}}^{-1}$), sites in similar environments are clustered together (Figure 16). The clustering reflects the degree of motional restrictions, with the second moment related to the averaging of the hyperfine anisotropy and the central line width to the averaging of the $g$-tensor. When motional restrictions increase, the averaging decreases and both the second moment and the line width of the resonances increase. Hence the second moment and line width can be used as semiempirical diagnostic tools to evaluate the secondary and tertiary structure of a labeled site.

5.2.1.3 Very Slow Motion ($\tau_r > 10^{-9}$ s) When $\tau_r > 100$ ns, conventional ESR line shapes are no longer sensitive to motion. The rate of angular exchange is too small to affect the hyperfine or $g$-anisotropy and the line shapes become insensitive to very slow motions. To study these biologically important motions, a related ESR technique was developed, STESR.

**Isotropic Motion.** In the presence of power saturation, the second harmonic out-of-phase ($V_2''$) line shape resembles an absorption spectrum (Figure 6c), with the intensity reflecting the effective relaxation at that point. Since effective relaxation is related to spectral diffusion and spectral diffusion is a function of the rotational correlation time, the $V_2''$ line shape reflects rotational mobility. The rate of spectral diffusion ($\tau_{sd}$) is a function of the resonant field $H_{\text{res}}$. Some field positions are more sensitive to angular rotation than others and $\partial H_{\text{res}}/\partial \theta$ varies across the spectral line shape. For instance, the rate of spectral diffusion is zero at the turning point $H^* = H_{\text{res}}(\theta = 0^\circ)$, but increases in the intermediate fields (Equation 42):

$$\tau_{sd}(H_{\text{res}})^{-1} = \left( \frac{8}{3\pi^2} \right)^2 \frac{a}{\partial H_{\text{res}}/\partial \theta} \frac{b^2}{\tau_r} \tau_{res}^{-1} \quad (42)$$

To the first approximation, the change of the signal intensity ($I$) at any field position is proportional to the change of the spin–lattice relaxation time due to spectral diffusion (Equation 43):

$$I(H_{\text{res}}) = I_0(H_{\text{res}}) \frac{T_1^{\text{eff}}(H_{\text{res}})}{T_1} \quad (43)$$

where $I_0$ is the rigid limit intensity in absence of motion and $T_1^{\text{eff}}$ is the intrinsic $T_1$ modified by spectral diffusion according to Equation (44):

$$T_1^{\text{eff}}(H_{\text{res}}) = T_1^{\text{eff}} \frac{1 + (I_0(H_{\text{res}})/T_2)\tau_{sd}(H_{\text{res}})^{-1}}{1 + T_1^{\text{eff}}\tau_{sd}(H_{\text{res}})^{-1}} \quad (44)$$

Since $T_1^{\text{eff}}$ is a function of the field position (spin angle with respect to field), it is customary to define the line height at precise positions in the spectrum: $L''$, $C'$ or $H''$ at $\theta = 35^\circ$ (two-thirds of the way between resonant field corresponding to $\theta = 90^\circ$ and $\theta = 0^\circ$) and normalize it to the intensity at $H^*$ ($L$, $C$ and $H$ positions) for which spectral diffusion is zero.

By substituting Equation (44) for the effective relaxation rate in Equation (43) a semiempirical expression for the $P'/P$ ratio dependence on $\tau_r$ is obtained (Equation 45):

$$\frac{P'}{P(H_{\text{res}})} = \frac{I_0(H_{\text{res}})}{I_0(H^*)} \frac{1 + a/\tau_r}{1 + b/\tau_r} \quad (45)$$

The parameters $a$, $b$ and $I_0(H_{\text{res}})/I(H^*)$ can be estimated from Equations (42) and (44) by numerically evaluating sensitivity $\partial H_{\text{res}}/\partial \theta$ at each spectral position. In practice, these values are obtained from fits to the experimental curves of line-height ratios from spectra of molecules undergoing Brownian diffusion with a known $\tau_r$. Spin-labeled hemoglobin or bovine serum albumin tumbling in media of a known viscosity (water–glycerol mixtures) is used for this purpose. The rotational rate of hemoglobin (the abscissa in Figure 17) is calculated from the Stokes–Einstein equation for a sphere of radius $r$, tumbling in a medium with viscosity $\eta$ (Equation 46):

$$\tau_r = \frac{4\pi\eta r^3}{3kT} \quad (46)$$

---

**Figure 17** Dependence of $V_2''$ diagnostic ratios on the rotational correlation time. The curves are simulated with Equation (63) using the parameter values from Table 1.

The parameter values listed in Table 1 were obtained for maleimide spin-labeled hemoglobin tumbling in different water–glycerol mixtures. In principle, these values should be transferable from one laboratory to another. In practice, each cavity is sufficiently different so that separate calibrations are often constructed. New calibrations are also necessary for different spin labels. Changes to the magnetic tensors and relaxation times alter STESR line shapes. In rare cases, full numerical calibrations are also necessary for different spin labels. When the major and minor axes are given by Equations (47) and (48), the parameter values listed in Table 1 were obtained from such calibration curves reflect rates for isotropic rotation. However, isotropic motion is not very common in biological systems. For example, the nonspherical shape of the diffusing molecules or the restoring potential of the media results in anisotropic motion. Intuitively, rotation about the long axis of a cylinder is faster than the tumbling motion around its short axis. Assigning an isotropic \( \tau_{\perp} \) to an anisotropic motion is obviously in error. For elongated molecules correlation times for rotation about the major and minor axes are given by Equations (47) and (48):

\[
\tau_{\parallel} = \frac{f_{\parallel}}{4kT(1 + f_{\parallel}/2f_{\perp})} \quad (47) \\
\tau_{\perp} = \frac{f_{\perp}}{6kT} \quad (48)
\]

where \( T \) is absolute temperature and the frictional coefficients \( f_{\parallel} \) and \( f_{\perp} \) are a function of the shape of the molecule.\(^{64,65}\) For a cylinder of length \( 2a \) and radius \( b \) the frictional coefficients are given by Equations (49) and (50):\(^{66}\)

\[
f_{\parallel} = 8\pi\eta a^2[0.96(1 + \delta_{\parallel})] \quad (49) \\
f_{\perp} = \frac{8\pi\eta a^2}{3[\ln(a/b) + \delta_{\perp}]} \quad (50)
\]

where \( \delta_{\parallel} \) and \( \delta_{\perp} \) are as given by Beth and Robinson (Equations 51 and 52):\(^{67}\)

\[
\delta_{\parallel} = 0.688 \left( \frac{b}{a} \right) - 0.202 \left( \frac{b}{a} \right)^2 \quad (51)
\]

\[
\delta_{\perp} = -0.661 + 0.891 \left( \frac{b}{a} \right) \quad (52)
\]

The anisotropic diffusion tensor \( (D) \) creates an additional complication. The effect of the molecular rotation on the spectral line shape is a function of the label orientation with respect to the diffusion axis. If the principal axis of diffusion is parallel to the \( z \)-axis of the spin label, the motion interconverts the \( x \)- and \( y \)-components only. If it is parallel to the \( x \)-axis, then the \( y \)- and \( z \)-components will be mixed. To describe fully anisotropic diffusion of the anisotropic tensor, six parameters are needed: three diffusion coefficients about the \( x \)-, \( y \)- and \( z \)-axes and three Eulerian angles describing the orientation of the diffusion tensor with respect to the magnetic tensor.

The problem is simplified if either the diffusion tensor \( (D) \) and/or the magnetic tensors \( (g \text{ or } A) \) are axially symmetric: the elements of the diffusion tensor are related to the correlation times by \( \tau_{\perp} = 1/(6D_{\perp}) \) with a corresponding expression for \( \tau_{\parallel} \). It has been shown that the effective correlation time obtained from the \( L''/L \) and \( H''/H \) line-height ratios of STESR spectra \( (m_1 = \pm 1) \) can be described in terms of \( D_{\perp}, D_{\parallel} \) and the angle \( \theta \) between the diffusion and magnetic tensor axis (Equation 53):\(^{68}\)

\[
\tau_{\parallel}^{\text{eff}}(\pm 1) = \frac{1}{3[D_{\parallel}\sin^2\theta + D_{\perp}(1 + \cos^2\theta)]} \quad (53)
\]

When \( \theta = 0^\circ \) the outer manifolds reflect \( D_{\perp} \) which defines the \( z \)- and \( x \)-( \( y \)-) element conversion \( (D_{\parallel} \) leaves the nitroxide \( z \)-direction unchanged). If \( \theta = 90^\circ \) the intensity of \( L''/L \) and \( H''/H \) is determined by \( D_{\parallel} \), which now interconverts the \( z \)- and \( x \)-, \( y \)-axes.

In some cases, anisotropic rotation is about a single axis and the motion can be described by a uniaxial model. The mobility of transmembrane peptides or proteins in lipid membranes is a good example. A uniaxial model, with a single diffusion tensor element \( D_{\parallel} \) and an angle \( \theta \) defining the relative orientation of the magnetic and diffusion axes, is sufficient to simulate STESR spectra of membrane-bound proteins.\(^{69}\) If \( \theta \) is not known, then \( \tau_{\parallel}^{\text{eff}}(\pm 1) \) gives an upper estimate of \( 0.5\tau_{\parallel} \ (\theta = 90^\circ) \). It is important to realize that the changes of the \( \theta \) angle, brought about by conformational changes, might result in STESR line-shape changes which can be mistakenly interpreted as changes in protein dynamics. A quick diagnostic for the presence of anisotropic motion is the comparison of the effective correlation times estimated from the \( C/C \) ratio and from \( L''/L \) \( (H''/H) \). If they agree,
then the motion is likely to be isotropic. If they are different, then either the overlap of the nuclear manifolds is different in hemoglobin calibration spectra (unlikely) or the motion is anisotropic. If the change in the STESR spectra is to be interpreted in terms of changed motional rate and not changed anisotropy of motion, then at least the ratio of the correlation times $\tau_{\text{eff}}(\pm 1)/\tau_{\text{eff}}(0)$ should stay constant.

Another motional model commonly encountered in biology is restricted diffusion. In such a model, the motion is isotropic but constrained in amplitude. The smaller the amplitude of motion, the slower is the apparent mobility derived from isotropic calibration. When the amplitude is $<30^\circ$, the effective correlation time can be a factor of 10 larger than the actual $\tau_r$ and for amplitudes $>60^\circ$, $\tau_{\text{eff}}$ approaches $\tau_r$. For small amplitudes, there is no isotropic line shape which will match the STESR spectrum of restricted motion. The amplitude effect is not just reflected in one or two places in the spectrum, but rather it is distributed across the whole line width.

An extensive review by Beth and Robinson deals with the effects of anisotropic motion on STESR spectra and the theoretical simulations of line shapes. Numerical simulations are based on the transition rate matrix which couples neighboring angular zones with the rate of angular reorientation. The SLE approach and spin density matrix method have also been used. Both approaches have been applied successfully to isotropic and anisotropic motional models. The continuous increase in computational speed bodes well for the routine application of STESR simulations to analyze experimental data.

### 5.2.1.4 Examples in Muscle Proteins

Microsecond motions are common for large macromolecular complexes (1 MDa) such as are present in muscle. The timescales of force generation, the actomyosin ATPase cycle and muscle activation coincide with the micro-to millisecond timescale of STESR, thereby making it the method of choice. The first application of the method established the dynamics of myosin, its subfragments and actin. Thomas et al. showed that the myosin head is capable of moving independently of the large myosin filament. Such motion was a prerequisite for force production. When bound to actin, in the rigor state (no ATP) the myosin heads were immobilized but when ATP was added the heads detached and were free to move.

Subsequent studies in muscle fibers at various intermediate states of the acto-myosin ATPase cycle have established a progressive decrease of catalytic domain mobility during the contractile cycle: the 10-μs motion of relaxed and weakly attached heads became 80 μs just before force was generated and was completely “frozen out” in the postpower stroke states of ADP and rigor. In the ADP state the head, although globally rigid, retained “breathing motions”, which were suppressed on the release of nucleotide. It is believed that this gradient in protein mobility reflects tighter and more stereospecific binding as myosin progresses through the contractile cycle (Figure 12).

The dynamics of the myosin head are complicated by the fact that this elongated protein does not behave like a rigid body. A comparison of the dynamics of the catalytic and regulatory domains revealed a three-fold difference in the rate of motion for the two domains. Moreover, the two domains were found to have dramatically different orientational distributions. These results highlight the complexity of the conformational changes in the actomyosin system: force generation is not synonymous with force transmission and both events involve changes of dynamics and orientation.

This complex behavior of myosin is in contrast to that of actin. Neither the orientation nor the dynamics of actin monomers, as probed by labels attached near the myosin binding site, were affected by head attachment. The absence of any orientational changes in contracting muscle fibers was also observed using spin-labeled toxin phalloidin bound rigidly to the interface between the actin monomers. This agrees with the current model of actin’s passive role in force production in providing “tracks” for myosin motor protein to “walk” on.

Force activation involves a complex pathway with subtle changes in protein–protein interactions. It is mediated by the conformations and dynamics of the participating molecules. Smooth muscle is activated via phosphorylation of myosin light chain 2, whereas skeletal muscle is regulated by a thin filament based system involving $\text{Ca}^{2+}$ binding to TnC. STESR spectra of phosphorylated myosin with a probe bound to myosin light chain 1 have implied increased motional freedom of the head. This finding supports a model in which unphosphorylated heads are tied to the surface of myosin filaments and inhibited from binding to actin. Phosphorylation abolishes the electrostatic attraction to the filament surface allowing the heads to interact with actin.

In skeletal muscle, binding of $\text{Ca}^{2+}$ to TnC initiates a signaling pathway from the thin to thick filament which ultimately activates muscle contraction. Biochemical changes in the affinity of myosin for actin and of TnC for $\text{Ca}^{2+}$ have a structural basis that is readily observed by both STESR and conventional ESR. The mobility and orientation of TnC (and TnI) has been found to be similarly affected by the binding of myosin heads to actin or by $\text{Ca}^{2+}$ binding to TnC. Interestingly, TnC was capable of sensing not only the binding of the myosin heads to actin but also the intermediate ATPase states.

### 5.2.1.5 Examples in Membranes

Rotational diffusion of membrane-bound proteins is often the best way of
determining the oligomerization state in their native environment without the possible dissociative effect of detergents. STESR of various integral proteins has revealed monomers such as rhodopsin,\(^{(88)}\) dimers such as cytochrome oxidase\(^{(89)}\) and ADP–ATP carrier\(^{(90)}\) or even higher oligomers such as Na, K-ATPase.\(^{(91)}\)

The biological significance of dynamic structural changes is best illustrated by the Ca-ATPase\(^{(92)}\), whose molecular dynamics correlate with transport activity.\(^{(93,94)}\) As shown by ST-EPR, allosteric interactions between Ca-ATPase polypeptide chains and catalytically important domain interactions involved in the transport cycle are regulated by both alterations in membrane lipid composition, anesthetics, and the regulatory protein phospholamban.\(^{(95–97)}\) Thus, physiological regulators of calcium transport modulate catalytically important motions and provide a structural basis for β-adrenergic stimulation in the heart.

Protein dynamics measured by STESR and conventional ESR have differentiated between two models of steroid biosynthesis in mitochondria: the shuttle mechanism and the ternary complex of adrenodoxin, P450 and adrenodoxin reductase. Adrenodoxin was found to form binary complexes (but not ternary complexes) with either P450 or adrenodoxin reductase, supporting a shuttle mechanism.\(^{(98)}\)

An excellent example of the potential of STESR in describing complex anisotropic motions is in the study of the transmembrane anion transporter Band 3 by Hustedt and Beth.\(^{(69)}\) The STESR spectra were simulated using a uniaxial model for protein rotation. The diffusion rate and the angle between the magnetic and diffusion tensor were freely floated in the least-squares fits to experimental spectra. The uniqueness of the solution was corroborated by the orientational study of Band 3 in oriented erythrocytes.\(^{(55)}\)

5.2.2 Mobility and Time Domain Methods

The measurement of the molecular dynamics by time-resolved ESR methods is still in its infancy. Specialized hardware is necessary to perform such experiments. Spectral diffusion due to the reorientation of spins can be observed either by recovery from saturation at the resonant field (saturation recovery ESR) or by arrival of saturation originally induced at some other nonresonant field (pulsed ELDOR). The initial promise of these methods was not fulfilled when it was shown that the nuclear relaxation, which couples different nuclear manifolds, contributed significantly to spectral diffusion. Combining pulsed ELDOR and saturation recovery differentiates between nuclear relaxation and rotational spectral diffusion and can be used to measure the true rotational correlation time.\(^{(99)}\)

2-D FTESR methods appear to be more promising. Nuclear relaxation is seen as cross peaks between the manifolds and can easily be distinguished from homogeneously broadened and spectral diffusion broadening.\(^{(100)}\) In the limits of fast motion, \(\tau_r\) is obtained directly from the homogeneous line width and is defined by the pure \(T_2\) (similar information is obtained from the spin-echo experiments). For slower motions, mixing time between the pulses is varied (2-D ELDOR) and the dependence of spectral broadening on mixing time is used to determine \(\tau_r\). Correlation times in the range 1–30 μs have been measured for small peptides tumbling in viscous media.\(^{(101)}\)

5.3 Kinetic Experiments

Elucidation of molecular mechanisms involves primarily two approaches: (a) entrapment of reaction intermediates with a subsequent reconstruction of the sequence of events and (b) transient kinetics in which the reactions are synchronized with the observed spectral changes. Each of these approaches have potential problems. In the “trapping” approach, the states have to be related to the kinetic intermediates. There are cases in which states trapped with substrate or product analogs are not lying on the kinetic pathway. On the other hand, transient experiments are easier to interpret, but technically more challenging owing to lower signal levels, fast acquisition times and difficulties in spectral assignment. The two approaches should be considered complementary. In an ideal world, “trapping” approaches should be used to identify and assign signals collected during transient experiments.

Historically, optical spectroscopy was used for transient kinetics owing to inherently higher sensitivity, but ESR is making substantial inroads.\(^{(102)}\) Recent advances in resonator design allow for millisecond resolution on microliter samples in the submillimolar concentration range.\(^{(103)}\) The DR developed for this purpose is capable of measuring millisecond kinetics in a single shot on 100 μL of a 40 μM sample with an 8-ms deadtime.\(^{(104)}\) The further development of this DR/stop-flow configuration allows the recording of a full spectrum within 100 ms.\(^{(105)}\)

Transient ESR was used to resolve the stages of channel formation in lipid membranes. Phospholipid vesicles and membrane channel collicin were mixed rapidly and the time course of the protein absorption to the membrane surface was clearly resolved from the insertion of the channel into the membrane.\(^{(106)}\) For collicin the process was fairly slow, with a timescale of seconds, but the formation of another channel annexin was followed on the millisecond timescale.\(^{(107)}\) The millisecond time resolution makes ESR a viable
alternative to optical methods in investigations of kinetic processes.

The photolysis of caged compounds, cATP and cCa$^{2+}$, to study conformational transients has been used primarily in the muscle field and in the study of Ca$^{2+}$-ATPase. A single ultraviolet (UV) pulse (10 ns in duration with an energy flux of 150 mJ cm$^{-2}$ at 351 nm) from an excimer laser is capable of liberating 0.5 mM ATP (Figure 18a and b). The magnetic field is locked into a position where the initial and final states display a large spectral difference and the intensity at that position is followed in time. In myosin, the pre- and post-ATP hydrolysis states have different mobilities at position is followed in time. In myosin, the pre- and post-ATP hydrolysis states have different mobilities at a labeled residue near the catalytic site, with correlation times of $\tau_1 > 100$ ns and $\tau_2 \approx 80$ ns. This mobility difference and the associated line-shape difference was utilized in measuring the rate of transition between the two states (43 s$^{-1}$) and was found to correspond to the hydrolysis rate of ATP$^{[108]}$ (Figure 18a and b). Similar experiments in muscle fibers, measuring both the orientation and the mobility, established that the rapid disorder of myosin heads follows nucleotide binding but precedes hydrolysis. These experiments also determined that the rate of hydrolysis is the same in fibers as in solution.$^{[102]}$

Transient ESR of the Ca$^{2+}$-ATPase following cATP photolysis revealed local domain changes around the labeled site which correlate well with the formation of the phosphoenzyme intermediate.$^{[109]}$ A larger and more motionally restricted label was also used to observe global changes, e.g. shape or oligomerization state. No such changes were observed by transient STESR during the ATPase cycle.$^{[110]}$

Biological photocycles encountered in rhodopsin and bacteriorhodopsin are special cases of cycles that are easily synchronized. The photoisomerization of retinal in bacteriorhodopsin initiates a series of proton transfer reactions via short-lived intermediates culminating in the loss of $H^+$ at the extracellular surface. Some 50 $\mu$s after photoactivation, an intermediate M decays to N when Asp96 transfers a proton to the Schiff base. During the decay of the N state, Asp96 regains a proton from the cytoplasmic site and bacteriorhodopsin reverts to the ground state, thereby completing the cycle. Labels have been attached to a number of cytoplasmic, interhelical and extracellular loops in the vicinity of Asp96 and their mobility was followed after irradiation with light.$^{[111-113]}$ Cytoplasmic sites and those near Asp96 all showed significant changes which coincided with the decay of the M state and recovered with the decay of the N state.$^{[112]}$ The efforts of Hubbell’s and Steinhoff’s groups to describe the molecular mechanism of rhodopsin and bacteriorhodopsin are an excellent example of the power of ESR methods to evaluate both static and transient molecular structures. In summary, the combination of high sensitivity, short mixing deadtimes, and temporal resolution makes ESR an increasingly popular method to study transient kinetics.

5.4 Protein Folding

In the last few years, site-specific spin labeling has been applied to protein folding problems.$^{[114,115]}$ The advantage of the ESR approach to protein folding lies in site specificity as the denaturation of local domains can be followed independently of global denaturation. This approach relies on differences in the mobility of spin labels in folded and denatured proteins. The folded protein provides steric restrictions due to secondary structure and tertiary contacts whereas the denatured one does not. The ESR spectra for the denatured fraction are a composite of sharp, motionally averaged line shapes in contrast to broader, immobilized spectra observed for the folded protein. Fractions of protein in each form are easily calculated by spectral subtractions and by line shape integrations.$^{[115]}$ Cooperativity and stability of the given region are determined from spectral titration with a denaturing agent, e.g. GdnCl, urea or heat. Differences in the melting of hydrophobic and aqueous surfaces of the $\beta$-strand pore of FepA receptor were observed by cysteine scanning of the polypeptide chain lining the channel. The hydrophilic surface was more stable and cooperative in the transmembrane portion of the strand than the

![Figure 18](image-url)
extramembraneous strand ends. The residues exposed to the lipid exhibited noncooperative melting and did not denature completely even at the highest concentrations of denaturants.\(^\text{116}\)

ESR is also capable of sensing multiphasic folding intermediates. Carbonic anhydrase was found to denature via an intermediate characterized by a compact and stable molecular core with a more dynamic periphery.\(^\text{117}\) In the presence of the chaperonin GroEL, the intermediate core was destabilized and partially melted, explaining how GroEL allows for the refolding of misfolded proteins.\(^\text{118}\) The development of new resonators, as mentioned previously, has facilitated detailed analysis of folding kinetics. The initial phases (<20 ms), ascribed to helix formation, were recently resolved by stop-flow ESR.\(^\text{104}\)

### 5.5 Ligand Binding

Two less well known applications of spin labeling are the determination of the binding of small ligands and the aggregation of large (the latter reviewed in section 5.7.4). The binding of small ligands is followed by changes in their mobility. Spin label analogs of ligands have sharp, motionally narrowed spectra when free in solution. Binding to a larger target slows the motion of the label and the spectra become broadened. Spectral resolution between the broad/bound species and the narrow/free ligands allows quantification of bound species and hence calculation of binding isotherms. The binding of mellitin to \(\alpha\)-crystallin\(^\text{119}\) and the binding of nucleotide analogs to ATPases were determined by this method. Binding studies are not limited to ligands carrying a spin label. Competition of unlabeled and labeled analogs is used to determine the \(K_d\) of unlabeled ligands. The binding of ATP, ADP, adenosine thiotriphosphate (ATPyS), adenosine imidotriphosphate (AMPPNP) and adenosine methylenetriphosphate (AMPPCP) to myosin was determined by the displacement of spin-labeled ATP.\(^\text{120}\)

A good example of ESR applications in ligand binding is the association of lipid spin labels with intrinsic membrane proteins. The differences in mobility are small and the spectra of bound and free labels are not resolved. Small broadening due to exchange between free and restricted environment was simulated to extract the equilibrium constant and the number of binding sites.\(^\text{61}\)

Finally, the binding of metals to proteins can be established by ESR. Mn(II) has a characteristic six-line spectrum when free in solution, but no signal when bound to protein. The decrease of free Mn(II) signal upon addition of a protein identifies the fraction of bound metal.\(^\text{121}\) As shown in the example with ATP analogs, displacement of bound Mn(II) by other metals can be used to determine their binding affinity.

### 5.6 Distance Measurements

ESR is capable of measuring short distances (2–25 Å) between selected sites. The method relies on the distance-dependent interactions between two spin labels (spin label–spin label method), or an interaction between a spin label and a paramagnetic metal (spin label–spin probe method). The physical basis for the coupling between the two spins is the exchange interaction \(J\) arising from the overlap of the orbitals of unpaired electrons and the dipolar interaction between magnetic moments of the two spin labels. The spin label–spin probe method relies on the enhancement of the relaxation of the spin labels by paramagnetic metals which have considerably faster relaxation rates and provide an efficient relaxation pathway for nitroxides.

#### 5.6.1 Spin Label–Spin Label Method

**5.6.1.1 Exchange Interaction, Distances <8 Å** At distances shorter than 8 Å, the \(\sigma\) or \(\pi\) orbitals of the neighboring unpaired electrons can overlap, creating a single spin state: singlet (spins are antiparallel) or triplet (spins are parallel) state. Unlike nuclear spin, electron spin coupling propagates both through space and through covalent bonds. Through-bond coupling drops off very quickly and is insignificant at a distance greater than a few bonds. The through-space coupling strength \(J\) is a function of the interspin distance \(r_{\text{dd}}\) (Equation 54). \(J\) diminishes exponentially, with a 1 Å interaction distance from the initial value of \(J_0 = 300\ G\).

In the strong exchange regime, when \(J\) is much larger than hyperfine interactions, the combined nuclear spin is 2 and the spectrum displays a five-line pattern. For weak coupling \((J < \lambda_0)\), the interaction asymmetrically broadens the low- and high-field resonances. The shift of the downfield edge of the low-field resonance in the presence of the second label \((\Delta H_{dd})\) is proportional to \(J\) and hence to the interspin distance.

\[
\Delta H_{dd} \approx J = J_0 \exp(-\beta r_{dd})
\]  

For example, a 0.1-Gauss broadening implies an interspin distance of \(~8\ Å\), defining the upper limit of the sensitivity.

Spin exchange in peptides labeled with two probes has been used to determine helical folds.\(^\text{122}\) Some proteins contain \(3_{10}\)-helices between \(\beta\)-strands or at the end of \(\alpha\)-helices and their detection in solution is difficult. Fiori and Millhauser utilized a difference of distance between the \(i\) and \(i+4\) residues along the \(\alpha\)- and \(3_{10}\)-helices to distinguish between the two helical forms. The \(i\) to \(i+3\) distances are similar in both helices (6–8 Å), but the \(i\) to \(i+4\) distance for the \(3_{10}\)-helix is outside the range of the exchange interaction (10–16 Å) and within the
range for an α-helix (7–11 Å). Placing pairs of labels in the $i$, $i + 3$ and $i + 4$ positions along the synthetic helices identified the predominantly α-helical regions in the N-terminus (equal broadening of $i$, $i + 3$ and $i$, $i + 4$ pairs) with the $2_{10}$-helix at the C-end (no broadening of the $i$, $i + 4$ pair). A comparison of 16- and 21-residue peptides revealed a length-dependent equilibrium between the α- and $3_{10}$-helices. Shorter peptides favored the $3_{10}$-helix whereas the longer peptides favored the α-helix.

Transition between the two helical forms might provide a mechanical pathway for allosteric mechanisms. The α-helix has more residues per turn and is significantly shorter, hence the $3_{10}$-helix to α-helix transition will mechanically pull on the neighboring domains.

5.6.1.2 Dipolar Coupling Distances: 8–25 Å In addition to the exchange interaction, neighboring spins experience local fields induced by their respective magnetic dipoles. The local fields can add to or subtract from the external field splitting each of the resonances. This dipolar interaction has an $r^{-3}$ dependence which results in discernible line-shape changes for distances up to 25 Å. The contribution of the exchange interaction for distances over 10 Å is negligible.

The strength of the dipolar interaction is a function of eight parameters: the interspin distance $r_{dd}$, the angle between the static magnetic field and the interspin vector and the six angles describing the orientation of each of the spin labels with respect to the interspin vector. Protein dynamics also affects these parameters on the timescale of the experiment: the global motion of the molecule modulates the angle with respect to the field, intradomain motions modulate the interspin distance and the interspin angles. The full solution of dipolar ESR line shapes in the presence of motion poses a formidable challenge.

The geometry of the NAD coenzyme bound to glyceraldehyde dehydrogenase (GAPDH) is the best example of the approaches taken to tackle this problem. Since GAPDH is a tetramer it can bind four molecules of coenzyme NAD. The relative orientation of the coenzyme was determined from the dipolar splitting of a spin label analog of NAD. Hustedt et al. used different microwave frequencies (9, 35 and 94 GHz) coupled with sophisticated fitting procedures to solve independently for most of the parameters listed above. The ESR structure was consistent with the geometry derived from molecular modeling using a crystal structure of the apo-enzyme.

Another example is the open form of α-helices in protic solvents. Alanine-rich peptides, incorporating the unnatural spin-labeled amino acid TOAC (2,2,6,6-Tetramethylpiperidine-1-oxyl-4-amino-4-carboxylic acid), showed a strong dipolar interaction for the $i$, $i + 4$ labeled peptides with less interaction between the $i$, $i + 3$ sites. Molecular modeling revealed a shorter interspin distance and larger backbone torsional angles, consistent with 3.8–3.9 residues per turn compared with 3.6 residues for a standard α-helix. The open configuration allows for the formation of additional hydrogen bonds with amide carbonyls while preserving helical hydrogen bonds. ESR proves to be an important tool in identifying subtle changes in helical folds induced by the local environment.

Short of solving the general case as above, two simpler cases are often encountered: (1) the static dipolar case in which all motions are frozen out, the labels are disordered on the surface of the protein and the protein itself is isotropically disordered in the magnetic field, and (2) the motionally averaged case in which the anisotropy of the dipolar interactions is averaged ($\tau_1 < 6$ ns) and the spectrum is homogeneously broadened by spin–spin interactions.

In the first case, the nitroxides and the sample are rigid and each of the resonance peaks are broadened by the Pake function given in Equation (55):

$$\Delta H_{dd} = \pm \frac{3g\beta(3\cos^2\theta - 1)}{4r^3}$$  \hspace{1cm} (55)$$

where $\theta$ is the angle of the interspin vector in the magnetic field.

Convolution of the resonances with the Pake pattern yields a characteristic line shape with dipolar wings in the low- and high-field regions of the spectra. The Pake function is obtained from the spectrum by a Fourier transform or by empirical calibrations. Empirical calibrations relate the line heights of the low- and high-field resonances to the line height of the central peak (Equation 56):

$$r_{dd} = 9.3 + \frac{0.77}{d_1/d} + 0.36A_{zz} - 1.76$$  \hspace{1cm} (56)$$

where $r_{dd}$ is in ångstroms and $A_{zz}$ is in gauss, $d$ is the line height of central resonance, and $d_1$ is the difference between low-field peak and high-field trough.

Alternatively, the Van Vleck relation between the second moment of the central resonance $M_2$ and $r_{dd}$ is used in obtaining the distance (Equation 57):

$$M_2 = \frac{3}{20} \frac{g^2\beta^2}{r_{dd}^6}$$  \hspace{1cm} (57)$$

where $r_{dd}$ is in ångstroms. The second moment is given by the Gaussian part of the peak-to-peak line width (Equation 58):

$$M_2 = \left( \frac{\Delta H_{pp}^G}{2} \right)^2$$  \hspace{1cm} (58)$$
The Pake broadening approach was verified for interspin distances of doubly labeled rigid synthetic polypeptides in which distances in the range 8–24 Å were predicted from the structure. The method was also verified for larger molecules by comparison with an X-ray determined structure of spin-labeled insulin. The interspin distances in a crystal were in excellent agreement with those found in solution by ESR. Distribution of distances due to protein flexibility in solution was found to be twice as large in solution as in the crystal. It is important to note that ESR is one of the very few techniques which can estimate conformational heterogeneity of a protein in solution.

Static dipolar broadening is rapidly gaining popularity. It was used in the analysis of helix packing of lactose permease in the membrane. Spin labels placed on surfaces which faced each other displayed dipolar broadening. Analysis of the extent of broadening as the label is moved around the helix identified the relative rotation of neighboring helices. Dipolar broadening was also used in the elucidation of the opening/closure of K-channels as described in detail in section 5.7.4.

The static dipolar approach (case 1) fails when the proteins are not rigid on the nanosecond timescale of an ESR experiment. If the spin mobility is high enough to modulate the anisotropy of dipolar interactions (Equation 59)

$$\tau_r \leq \left( \frac{g^B \Delta H_{dd}}{h} \right)^{-1} = \left( \frac{3\pi g^2 B^2}{r_{dd}^3} \right)^{-1}$$  (59)

the rotational modulation of the interspin vector results in the broadening related to both the distance and the correlation time (Equation 60):

$$\Delta H_{dd} = \frac{3}{10} \frac{g^B}{r_{dd}^3} \tau_r \left( \frac{5}{1} + \frac{2}{1 + 4v^2 \tau_r^2} \right)$$  (60)

Line-shape comparisons of singly and doubly labeled samples reveal the extent of dipolar broadening from which the $r_{dd}$ distance is calculated assuming (or measuring) an appropriate correlation time for the molecule. McHaourab et al. tested this approach on a series of labeled sites in T4 lysozyme (8 Å < $r_{dd}$ < 23 Å) and found them to be in excellent agreement with the structure of the protein (Figure 19a and b). Note that the motional modulation regime is a function of both the interspin distance and the rotational correlation time, e.g., dipolar interactions of labels 15 Å apart are averaged for motions with correlation times of ≤ 6 ns.

The above examples illustrate the static and motionally averaged cases of spin–spin interactions. However, often the precise mechanism of spin–spin interactions is not known as there are contributions from static dipolar interactions, from the rotational modulation of the interspin vector and from the modulation of the interspin distance. Although there is currently no theory fully describing the changes in the ESR line shape, the presence of line-width broadening is always indicative of two labels being in the range 10–20 Å from each other. Even the simplest, qualitative statement of spin–spin distance can yield important structural information. The presence of spin–spin interactions has helped to elucidate changes in the topology of the cytoplasmic portion of rhodopsin following light activation. It has explained how rhodopsin initiates the phosphorylation cascade by rhodopsin kinase.

Interested readers are directed to an excellent review by Hustedt and Beth.

5.6.1.3 Very Long Distances: > 25 Å The upper limit of 25 Å for the detection of dipolar interactions is defined by an observable broadening: ~3 G for inhomogenously
broadened samples of rigid samples and 0.2 G for the sharp, motionally narrowed line shapes. This limit can be extended by time-resolved techniques, which unlike the continuous-wave methods do not rely on line broadening. A variety of pulsed ESR methods have been developed for this purpose. Double electron–electron resonance (DEER) is one method in which the spin echo is observed as a function of time of an intervening pulse applied at a second frequency, \(^{131,132}\) or at the same frequency as in “2 + 1” resonance. \(^{133}\) In both cases, an amplitude of the spin echo is modulated by Pake dipolar interactions which are extracted by Fourier transformation of the echo modulation. In model compounds, the distances recovered by DEER ranged between 20 and 33 Å, \(^{132}\) whereas the “2 + 1” scheme elucidated an interspin distance of 35 Å between nitroxides attached to β-93 cysteine in tetrameric hemoglobin. \(^{133}\) Double quantum 2-D FTESR is the most recent technique that looks directly at spin–spin interactions i.e. the filtering out of a “normal” ESR spectrum originating from isolated spins. This method has been tested on solid polyproline peptides with an interspin distance of 18 Å. \(^{101}\)

5.6.2 Spin Label–Paramagnetic Metal Method
An entirely different way of determining distances is by coupling an unpaired spin of a nitroxide radical to a fast-relaxing spin of a paramagnetic metal, e.g. Cu(II) or Fe(III). The spin–lattice relaxation times of many metals are three orders of magnitude faster than those of nitroxide spin labels and thus, when coupled to nitroxides, they provide an efficient relaxation path. The relaxation enhancement can be detected by either increased Lorentzian broadening or directly by the shortening of \(T_2\) or \(T_1\) of the spin label in the presence of the metal (Equation 61):

\[
\Delta T_{1s} = \frac{\mu^2 r^2}{6\rho T_{1h}} \left( \frac{4}{5(w_1 - w_2)^2} + \frac{24}{5(w_1 + w_2)^2} + \frac{12}{5w_1^2} \right)
\]  

Equation (61)

All three methods have been tested in spin labeled hemoglobin in which a nitroxide at residue 93 of the β-chain was coupled to Fe(III) bound to the heme. The distance of 15 Å between the label and iron was in excellent agreement with molecular modeling. \(^{134}\)

The metal relaxation is not limited to naturally occurring metal binding sites. Site-specific spin labeling has recently been extended to the engineering of metal binding sites.

Voss et al. engineered Cu(II) binding sites to T4 lysozyme and lactose permease by introducing histidine residues in consecutive turns of the α-helix. \(^{135,136}\) Spin labels were placed between 8 and 18 Å away from the metal site by cysteine mutagenesis. The ESR line shapes were broadened by paramagnetic Cu(II) chelated by the histidine residues. Binding of diamagnetic metals did not affect the line shape. The spectra were analyzed in terms of the dipolar model of Leigh, \(^{137}\) which relates line-shape broadening to the interspin distances \(r_{dd}\) and metal relaxation time \(T_{1m}\) (Equation 62):

\[
\Delta H_{dd} = \frac{g^2 \mu^2 T_{1m}}{\hbar^2} (1 - 3 \cos^2 \theta)^2
\]  

Equation (62)

where \(\mu\) is the magnetic moment of the metal.

A convenient experimental parameter is the amplitude of the central line. The amplitude decreases with decreasing spin–spin separation. Calibration curves derived from computer simulations were used to estimate the interspin distances in two model systems, lactose permease and T4 lysozyme. Excellent agreement was found, not only for the rigid samples for which Leigh’s model was originally developed, but also for motionally narrowed spectra due to the mobility of the nitroxides with respect to the protein. For Leigh’s model to hold, the interspin vector must not move on the same timescale as dipolar interactions, which is \(T_1\) of the metal. This is satisfied for molecules larger than 15 kDa (\(\tau_r > 6\) ns) and for metals such as Cu(II) where \(T_1\) is 1–3 ns. The distances obtained for T4 lysozyme in solution at room temperature were approximately 1 Å shorter than those obtained from frozen proteins. \(^{136}\) This small underestimation of the distance is compensated by the biological advantage of performing experiments at room temperature and by the increased fidelity in measurements of small-amplitude changes in sharper, motionally narrowed spectra. Another elegant application of this method involved the determination of helix packing in lactose permease. Interspin distances between three helices labeled with nitroxide labels and a metal site containing Cu(II) determined the relative orientation of the helices and their relative tilt. \(^{138}\)

Current this method is limited to distances between 10 and 20 Å for Cu(II) with the X-band. Inspection of Leigh’s Equation (61) suggests that the distance range might be extended to \(\sim 50\) Å by using lower ESR frequencies (S-band), metals with a larger magnetic moment (Gd\(^{3+}\)) or shorter \(T_{1}\) (Ni\(^{2+}\)) and also by direct measurement of relaxation times. \(^{139}\)

5.6.3 Collision Exchange
A variation of spin–spin interactions is the relaxation of spin labels by collisions with soluble paramagnetic agents such as metals or O\(_2\). Collisions lead to the HSE, enhancing spin–lattice relaxation according to Equation (63):

\[
\Delta T_{1}^{-1} = kW_r
\]  

Equation (63)
where \( k \) is a factor accounting for the efficiency of collisions and statistics of diffusion in two or three dimensions and \( W_s \) is the bimolecular collision frequency. The collision frequency is of interest because it reflects the accessibility of the labeled site to the relaxant. Comparison of \( W_s \) for various sites reveals which residues are exposed or hidden and their secondary structure content and identifies tertiary interactions.

Relaxation enhancement is measured directly by pulse methods (saturation recovery or spin echo ESR) or by continuous-wave power saturation. The amplitude of the ESR signal increases linearly with the microwave magnetic field \((H_1 \propto P^{1/2})\) until the Boltzmann equilibrium population difference is perturbed and the signal between excited and ground states decreases. Samples with a long \( T_1 \) saturate easily and addition of relaxing agents relieves this saturation (Figure 20).

The peak-to-peak amplitude \((A)\) of the first-derivative spectrum is given by Equation (64)

\[
A = \frac{A_0 \sqrt{P}}{1 + (\sqrt{2} - 1)(P/P_{1/2})^{\varepsilon}}
\]

where \( \varepsilon \) depends on the resonance line shape and varies between 0.5 for purely Lorentzian and 1.5 for Gaussian line shapes; \( A_0 \) is an instrument scaling factor and \( P_{1/2} \) is the half-saturation power (the power at which the signal is half of what it would be in the absence of saturation). \( P_{1/2} \) is determined either graphically or by the fitting of experimental curves to Equation (64). The \( P_{1/2} \) value is then used in calculating \( T_1 \) according to Equation (65):

\[
T_1 = \frac{2^{2/3} - 1}{\sqrt{2} \Lambda^2 P_{1/2} T_2}
\]

where \( \Lambda \) is an instrumental factor which depends on the power-to-magnetic field conversion of the resonator. Since \( T_2 \) for nitroxides is 2–3 orders of magnitude smaller than \( T_1 \) and because \( T_2 \) is proportional to the peak-to-peak line width of the central line \((T_2 \propto 1/\Delta H_0)\), the collision frequency is determined from Equations (63) and (65) (Equation 66):

\[
W_s \propto \Delta P_{1/2} T_2 = \frac{\Delta P_{1/2}}{\Delta H_0}
\]

In order to account for differences in resonators and spectrometers between various laboratories, a dimensionless accessibility parameter \( \pi \) was defined; \( \pi \) normalizes \( W_s \) to the half-saturation power and line width of a diphenylpicrylhydrazyl (DPPH) standard.

Trends in accessibility to various relaxing agents are used to determine the local environment of spin labels. The relaxants can be nonpolar such as \( \text{O}_2 \) partitioning into lipid bilayers, or polar with preference for the aqueous phase. The latter includes neutral relaxants such as \( \text{NiAA} [\text{nickel(II) acetylacetone}] \) and \( \text{NiEDDA} [\text{nickel(II) ethylenediaminediacetate}] \) and charged relaxants such as \( \text{CROX} [\text{potassium tris(oxalatochromate)}] \).

An important application of collisional relaxation is the determination of the secondary structure of peptides and proteins. Patterns of collisional accessibility along the polypeptide chain can reveal \( \alpha \)-helical folds, \( \beta \)-sheet strands, immersion in membranes and chain tilt within the membranes. These applications are described at length in section 5.7.2.

### 5.7 Structural Biology

The advent of site-specific spin labeling established ESR as a structural technique. Comparison of the relaxations enhancement of four labeled cysteine mutants of bacteriorhodopsin identified membrane embedded and surface exposed residues. Since then, these approaches have been refined and extended to establish (a) the topology of membrane bound proteins, (b) the secondary structure of proteins by cysteine scanning and following trends in accessibility and mobility of residues and (c) the tertiary folding of proteins by distance measurements between engineered sites. Most of the examples discussed below are from work of Hubbell et al.
5.7.1 Side-chain Environment – Immersion in Membranes

Differential effects of nonpolar (O$_2$) and polar (NiAA, CROX) relaxants are used to measure the immersion depth of membrane proteins. This technique relies on opposite concentration gradients for polar and nonpolar relaxants within lipid membranes. The concentration of nonpolar reagents increases with the immersion depth and the concentration of polar reagents decreases. The further the nitroxide is from the aqueous interface, the stronger is the relaxation enhancement by nonpolar reagents and the weaker is the effect of polar relaxants. The difference ($\Phi$) between the polar and nonpolar reagents as defined in Equation (68) is thus a function of the immersion depth:

$$\Phi = \ln \frac{\Delta P_{\text{nonpolar}}^{1/2}}{\Delta P_{\text{polar}}^{1/2}}$$

Calibration curves of $\Phi$ are constructed using lipid spin labels with nitroxides at defined positions along the acyl chains and these curves are used to determine the immersion depth of labels attached to membrane-bound proteins (Figure 21a and b).

This relatively simple method, when used in conjunction with cysteine scanning, differentiates between membrane-bound and solvent-accessible surfaces of membrane-associated proteins or peptides. As the nitroxide is moved along the length of a polypeptide chain, $\Delta P_{1/2}$ for the polar agent shows minima and maxima for the residues interacting with the lipid bilayer and the surface-exposed residues, respectively. The nonpolar agent has a similar pattern of minima and maxima, but it is offset by 180° with respect to the polar relaxant, i.e. maximum relaxation will be observed for the residues interacting with the membrane and minimum relaxation for water-exposed residues. A similar phase shift is observed for the residues of helices lining the aqueous pores of channels. Residues facing the lumen of the pore show maximum relaxation enhancement for polar agents (minima for the nonpolar oxygen), while the residues facing the membrane environment have maxima for oxygen and minima for CROX, NiAA and NiEDDA.

Such is the case for the ferric enterobactin receptor FepA, the transmembrane $\beta$-strand of which was found to line an aqueous channel. The maxima of accessibility to NiEDDA was alternating with maxima to O$_2$, identifying the $\beta$-strand face as lining the channel and the side of the $\beta$-strand facing the lipid bilayer.$^{[143]}$

Similar results have identified residues lining the aqueous channels in collicin,$^{[144]}$ diphtheria toxin$^{[145]}$ and annexin.$^{[107]}$

![Figure 21 Immersion of a polypeptide chain in the lipid bilayer. Differential accessibility to polar (○) and nonpolar (●) relaxants, $\Phi$, identifies the distance from the aqueous surface. Calibration curves of $\Phi$ are constructed using lipid spin labels with nitroxides at defined positions along the acyl chains.$^{[143]}$ (Reproduced with permission from C.S. Klug, W. Su, J.B. Feix, Biochemistry, 36, 13027–13033 (1997).)](image)

5.7.2 Secondary Structure Determination

Cysteine scanning also allows for secondary structure determination. One method, based on the exchange interactions between nitroxides attached to the $i, i+3$ and $i, i+4$ residues, identifies $\alpha$- and $3_{10}$-helices and was discussed in section 5.5.1.1. Other methods rely on changes in nitroxide mobility and accessibility to relaxing agents. The periodicity of steric interactions varies along the polypeptide chain, which in turn determines the nitroxide mobility and/or periodicity of relaxation effects.$^{[146]}$ For example, an $\alpha$-helix in an unevenly
solvated environment (owing to the interaction with a membrane surface or another polypeptide chain) shows a pattern of flexibility and solvent accessibility with a 3.6-residue periodicity. β-Strands, on the other hand, will display a two-residue periodicity (Figure 22a and b).

This characteristic periodicity of 3.6 residues was observed for a number of helices of transmembrane proteins: rhodopsin,\(^{146–149}\) collicin,\(^{143}\) K-channel\(^ {32}\) and the soluble protein T4 lysozyme.\(^ {31}\) Periodicity of β-strands was observed for the transmembrane protein FepA receptor\(^ {143}\) and water-soluble α-crystallin.\(^ {150,151}\) In some cases ESR has extended the structural information obtained by other methods, for example interhelical loops in rhodopsin.\(^ {147}\) However, in other cases, the secondary structure determined by ESR was the only available source for example FepA receptor\(^ {143}\) and α-crystallin.\(^ {150}\)

An interesting use of SDSL ESR is to extend monomeric (subunit) structures determined by NMR and X-ray crystallography to the structures of functioning macromolecular complexes. The monomeric structure of the soluble (nonfunctional) form of the membrane pore annexin has been solved by X-ray crystallography. A mobility and accessibility profile of 26 single cysteine mutants in the helix–loop–helix motif has revealed a dramatic structural transition when annexin is inserted into the membrane to form a continuous, transmembrane α-helix. As was expected for a membrane pore made of the annexin trimer, one side of the helix was found to be highly solvated.\(^ {152}\)

5.7.3 Tertiary Structure: Conformational Changes

The greatest potential for the above methodologies is the determination of tertiary structure. The current rate of structure determination by X-ray crystallography or NMR (≈1000 per year) is too slow to solve for all 120,000 gene products. Fortunately, most proteins are built from well-defined, common structural motifs, but are packed in different ways to give proteins their unique three-dimensional structure. It seems that instead of solving ab initio the atomic structure of each protein it will be simpler to determine the relative arrangement of common structural motifs. For instance,
a few chosen mutations can quickly establish whether
given helices or β-strands are in a parallel or antiparallel
arrangement.\textsuperscript{113,153)}

Qualitative information about tertiary structure is
obtained from mobility and solvent accessibility values,
both of which are limited to sites of tertiary contacts,
e.g. \( \pi \) (O\(_2\)) values are 0–0.05 for buried sites and 0.3
for solvent-accessible surface sites.\textsuperscript{(119)} Additionally, in-
phase tracking of accessibility to polar and nonpolar
reagents and tracking of mobility patterns identifies
surface residues and residues buried within a protein core.
The surfaces involved in helix packing in rhodopsin\textsuperscript{(147,148)}
and colicin\textsuperscript{(144)} and β-strand packing in α-crystallin\textsuperscript{(151)}
have been identified by this in-phase behavior.

The tilt angle of polypeptide chains within lipid mem-
branes is easily determined from the immersion depth of
selected residues (see section 5.7.1). The immersion depth
is calculated from the \( \Phi \) parameter (ratio of nonpolar to
polar accessibility), which is calibrated in terms of the
distance from the membrane surface of lipid spin labels at
defined positions. The average depth (\( d \)) of consecutive
residues is compared with the distance along the chain
\( d_0 \). The tilt of the chain with respect to the bilayer
normal is given by Equation (69):
\[
\alpha = \cos^{-1} \left( \frac{d}{d_0} \right) \tag{69}
\]
For β-barrels, the tilt information, combined with number
of β-strands, can be used to estimate the diameter of the
barrel.\textsuperscript{(144)}

Most of the examples identifying conformational
changes are from membrane-bound proteins. In rhodop-
sin, helices flanking the ionone ring of retinal have
been labeled with nitroxides and the interspin distance
tracked upon photoisomerization of the retinal.\textsuperscript{(130,154)}
The observed rigid body rotation, with an associated
change of the tilt angle in one of the flanking helices,
resulted in increased accessibility of the cytoplasmic
loop. Increased exposure of the loop facilitates binding
of transducin to rhodopsin, which is the first step in
the phosphorylation cascade of signal transduction
pathway.

Conformational changes accompanying insertion into
a membrane and pore formation were observed by ESR
for the small cytosolic protein annexin. A water-soluble
monomer with a helix–loop–helix motif was rebuilt to
form a continuous transmembrane helix in the presence
of Ca\(^{2+}\). The formation of long helix induced
membrane insertion of annexin.\textsuperscript{(107)} In another example,
smaller conformational changes were observed by vary-
ing the lipid environment of transmembrane proteins.
Reconstitution of lactose permease into proteolipo-
somes induced a small 2-Å movement of neighboring
helices.\textsuperscript{(127)}

A particularly rewarding example is that of conforma-
tional changes in T4 lysozyme: two structures solved by
X-ray crystallography implied a hinge movement which
opened the active site by 8 Å. Using strategically placed
cysteines near the active site, this predicted opening of
the active site was verified in solution.\textsuperscript{(129)} In addition to
corroborating the presence of the two conformers, ESR
was able to measure an equilibrium of closed and open
structures, yielding a unique estimate of activation energy
associated with catalysis.

The most spectacular application of ESR to the ter-
ary/quaternary structure of proteins was that of the
bacterial potassium channel by Perozo.\textsuperscript{(32,128)} Nearly a
third of the entire protein including two transmembrane
helices and the interhelical region flanking a selectiv-
ity filter have been scanned with spin labels. This is a
total of 62 mutants for the 160 amino acid polypeptide
chain. The channel is formed by the tetrameric assem-
bly of the two helices, with one helix (TM2) forming
an aqueous pore and the other helix (TM1) located on
the periphery. The structure has been solved independ-
ently by X-ray crystallography\textsuperscript{(156)} and by ESR from
accessibility and mobility profiles.\textsuperscript{(32)} The ESR protein
structure determination was further extended to the
structural description of the channel opening. The chan-
nel is activated by lowering the pH. Sequence profiles
of mobility and interspin distances were compared for
the open and closed forms, revealing a physical opening
of the central pore. The open form was brought upon
by a rigid body rotation and tilting of the TM2 helices
with an accompanying movement of the peripheral TM1
helices.\textsuperscript{(128)}

5.7.4 Assembly of Polypeptide Chains: Quaternary
Structure

Differences in mobility between monomers and oligomers
can be used to identify the oligomerization state of pro-
tein. For small proteins, ESR line shapes are motionally
narrowed, whereas the spectra of aggregates are consid-
érably broader. Spectral resolution of monomeric and
oligomeric forms in a composite spectrum allows for the
determination of their respective concentrations in solu-
tion and hence thermodynamic parameters of oligomer
formation. Oligomerization in a variety of solvents of
eccropin AD, a small ion channel, was studied in this
way.\textsuperscript{(157)}

The kinetics of the formation of amyloid plaques were
monitored by the disappearance of the sharp central
line of the spin-labeled amyloid protein monomer.\textsuperscript{(158)}
Monomers were found to aggregate initially into an
amorphous plaque precursor in which the protein
was in equilibrium between soluble monomers and
the aggregated protein. The precursor was an initi-
atation site for fibril formation of which the amyloid
plaques are subsequently formed. Characterization of various assemblies and the equilibria between monomers and aggregates are of direct interest in understanding the molecular basis for diseases such as Creutzfeldt–Jacob (“mad cow disease”) and Alzheimer’s disease.

An alternative way of following the formation of aggregates is to utilize spin–spin interactions. Interacting monomers lead to a broadening of the ESR spectra, provided that the labels are within the range of spin exchange or dipolar interactions. Spin-labeled insulin B chain was found to aggregate on reduction of the interchain disulfide bonds, but the presence of α-crystallin was found to prevent aggregation. In the absence of crystallin, the spectra of B insulin displayed a broad Lorentzian pattern, characteristic of closely placed spins. This turned into a normal powder pattern upon binding to crystallin.\(^\text{119}\)

Titration of spin–spin interactions with unlabeled proteins can be used to estimate the number of monomers forming an oligomer. As the concentration of unlabeled monomers increases, the probability of spin–spin interactions decreases and dipolar broadening is relieved leading to an increase in signal amplitude. For small oligomers, dilution with small amounts of unlabeled protein results in a greater increase of signal amplitude than for larger oligomers. The titration follows a binomial expansion and has been used to establish that the membrane-bound form of annexin is a trimer.\(^\text{107}\)

This qualitative approach has been used for annexin pores. While the crystal structure of the soluble form of annexin suggested a hexameric assembly, nothing was known about annexin in membranes. Among the possibilities were a trimeric ring and a hexamer consisting of stacked trimers. To distinguish between these alternatives, cysteines were introduced at the interface between the monomers forming a trimer and on the interface between the trimers forming a putative hexamer. In the soluble form, no dipolar interactions between any of the sites were observed, consistent with the monomeric form in solution. Addition of Ca\(^{2+}\), which triggers membrane binding, resulted in the broadening of the spectra within the trimer but not between the trimers, proving that a trimer and not a hexamer was forming the pore.\(^\text{107}\)

6 CONCLUSION

ESR of protein is currently enjoying a renaissance of sorts. In addition to its contributions in studies of protein dynamics and orientation, ESR is being increasingly used as a structural technique. The advances of molecular biology facilitate targeting of chosen domains or scanning of the whole structure with spin labels. Comparison of dynamics, accessibility and distances at consecutive positions along the polypeptide chain is used in the determination of the secondary, tertiary and quaternary structure of proteins, which is of enormous importance in the post-genomic era. It is likely that the ease of determination of relative orientation of known domain motifs will make ESR a method of choice in high-throughput structural biology.

Technical advances in ESR, which include new probes, FTESR, higher magnetic fields, increase in absolute sensitivity, spectral dispersion and diversity of applications bode well for the continued development of ESR spectroscopy. Lastly, the development of powerful computational simulations makes ESR user-friendly and increases the number of ESR practitioners outside the die-hard community of spectroscopists.

1 INTRODUCTION

Fluorescence spectroscopy and its multiple applications to protein analysis, and to the life sciences in general, have undergone rapid development during the past decade. This progress appears to be driven on two levels. First, numerous technical advances in time resolution, methods of data analysis, and improved instrumentation have enabled researchers to probe the structural and dynamic features of proteins, membranes and nucleic acids, to acquire multidimensional (space–time) microscopic images of the distributions of various molecules in cell cultures, to follow conformational changes of single molecules, etc. These developments, pioneered by a handful of research groups, have spilled over into multiple areas as diverse as basic analytical chemistry and practical clinical applications.

The second, and sometimes under-appreciated, level of development of fluorescence spectroscopy in studies of biological macromolecules involves the proliferation of the basic technique. This progress is driven mainly by researchers whose primary scientific interests lie well outside the field of spectroscopy, and who, while admiring the elegance of the custom-designed multiphoton excitation experimental scheme, might not necessarily want to implement one in their own laboratory. Instead, they will use a commercially available fluorimeter, almost standard equipment these days in many laboratories involved in biochemical and biophysical studies. Nevertheless, their studies have produced not only numerous answers to a variety of important biological problems but have broadened the range of fluorescence techniques as well.

The availability and simplicity of basic data acquisition and analysis are important practical features behind the popularity of fluorescence as compared to other spectroscopic techniques. Yet this simplicity does not appear to compromise its main advantages, one of which, exceptional sensitivity, allows routine detection of fluorescent substances on a subnanomolar scale on the one hand, and provides the ability to collect data in a kinetic regime during fast submillisecond reactions on the other. Applications of fluorescence spectroscopy to protein and peptide analysis are governed by three principal factors: (1) the dynamic nature of the signal, (2) its localized nature, and (3) its redundancy. Fluorescence is a dynamic phenomenon and the
lifetime of the excited state is sufficient for a variety of chemical and physical reactions to take place prior to emission. The usual nanosecond time-window of fluorescence is normally shorter than that of other dynamic techniques (e.g. nuclear magnetic resonance (NMR), electron paramagnetic resonance (EPR)). Fluorescence spectroscopy is essentially a probe technique sensing changes in the local environment of the fluorophore, which distinguishes it from generalized techniques, such as calorimetry, far-ultraviolet circular dichroism (CD), and infrared (IR) spectroscopy. Also, various possibilities of structural rearrangements in the environment of the fluorophore may lead to a similar fluorescence signal. None of these features taken alone is either beneficial or detrimental. Although they can complicate interpretation of the experimental result, they also can be exploited to obtain unique structural and dynamic information.

Fluorescence spectroscopy and its various applications have been reviewed over the years in several excellent publications, e.g. basic and advanced textbooks, monographs and specialized editions. This article is not intended as a condensed version of the material in those contributions. Instead it focuses on two tasks: first to provide an overview of the fluorescence phenomenon in proteins, and second to illustrate applications of fluorescence spectroscopy in state-of-the-art (but not necessarily high-tech) studies. The goal is to concentrate on fundamental principles and advanced applications.

1.1 What is Measured in a Protein Fluorescence Experiment?

The four principal aspects of the fluorescence phenomenon are: energetics, probability, kinetics and vectoriality. Each can be studied experimentally by measuring the intensity of the emitted light as a function of wavelength (or wavenumber) comprises the fluorescence spectrum. The position of the emission spectrum reflects changes in energetics of the excited and ground state between excitation and emission of a photon. In practice the position of the emission band is expressed as a wavelength of the maximum $\lambda_{\text{max}}$.

Total intensity of the emission at all wavelengths is related to fluorescence quantum yield, $q$. Quantum yield is defined as a ratio of the number of emitted quanta to the number of absorbed quanta. It reflects the probabilities of various photochemical and photophysical processes leading to radiational or radiationless deactivation of the excited state.

The time-dependence of fluorescence intensity following excitation in the ensemble of fluorophores is related to the excited state lifetime, $\tau$. This kinetic parameter characterizes the average time a molecule spends in the excited state before emitting the photon:

$$I(t) \sim e^{-t/\tau}$$

More often than not, fluorescence intensity follows a more complex law of decay than simple exponential (see section 2.3). Two experimental schemes allowing determination of the fluorescence lifetime are known as pulse domain and frequency-modulation domain spectroscopy (for more on lifetime measurements see Lakowicz[1,3]).

Anisotropy, $r$ (along with the interchangeably related polarization, $P$), is a vectorial characteristic reflecting changes in the direction of the emission transition moment with regard to the excitation transition moment. Anisotropy is affected by the relative orientation of the dipoles in the ground and excited states and by changes in the orientation of the excited state with respect to external (laboratory) coordinates due to the molecule’s rotation or radiationless energy transfer to another molecule prior to emission. Anisotropy and polarization are defined in Equations (1) and (2) by intensities of vertically ($I_\parallel$) and horizontally ($I_\perp$) polarized light measured when excitation light is vertically polarized:

$$r = \frac{I_\parallel - I_\perp}{I_\parallel + 2I_\perp} \quad (1)$$

$$P = \frac{I_\parallel - I_\perp}{I_\parallel + I_\perp} \quad (2)$$

Anisotropy and polarization can be measured in a steady-state and kinetic regime (for more on anisotropy measurements and their applications see Steiner[8]).

The ratio of intensities in the absence, $I_0$, and in the presence, $I$, of an external quencher at concentration $[Q]$ is used to determine a Stern–Volmer constant, $K_{SV}$, as shown in Equation (3):

$$\frac{I_0}{I} = 1 + K_{SV}[Q] \quad (3)$$

If the changes in lifetime follow the changes in intensity, the quenching is called dynamic and the biomolecular quenching rate, $k_q$, can be determined using Equation (4):

$$\frac{\tau_0}{\tau} = 1 + K_{SV}[Q] = 1 + k_q [Q]$$

The biomolecular rate gives information on chromophore accessibility to the aqueous phase and on the distribution.
of charges surrounding the fluorophore if a charged quencher is used. In the case of static quenching, only the intensity decreases with addition of quencher while the lifetime remains the same (for more on quenching measurements and their applications see Eftink\(^9\)).

Another useful parameter is the efficiency of the long-range energy transfer, \( E \), between an initially excited molecule (donor) and another chromophore (acceptor). Efficiency of this dynamic process can be calculated from either intensity or lifetime of donor alone \( (I_D, \tau_D) \) and in the presence of acceptor \( (I_{DA}, \tau_{DA}) \) as shown in Equation (5):

\[
E = 1 - \frac{I_{DA}}{I_D} = 1 - \frac{\tau_{DA}}{\tau_D}
\]

(5)

Efficiency of transfer is used to estimate the distance between donor and acceptor, \( R \), according to Förster theory, as shown in Equation (6):

\[
E = \frac{R_0^6}{R_0^6 + R^6}
\]

(6)

where \( R_0 \) is a Förster distance for half-transfer and is a characteristic of a donor–acceptor pair and its environment (for more on energy transfer measurements and their applications see Cheung\(^{10}\), Wolber and Hudson\(^{11}\) and Wu and Brand\(^{12}\)).

It is important to keep in mind that neither distance, nor quenching rate, nor strictly speaking lifetime are measured in a fluorescence experiment. All these important parameters are derived from the basic measurements of intensity, using more or less restrictive assumptions (e.g. absence of nonspecific perturbations after introduction of the acceptor fluorophore, or fluorescence decay being adequately described by a sum of exponential components) and therefore are to some extent model-dependent.

2 PROTEIN FLUORESCENCE

2.1 Spectral Properties of Protein Fluorophores

2.1.1 Tryptophan and its Derivatives

Absorption of tryptophan is due to \( \pi \rightarrow \pi^* \) transitions in the indole ring (1). The short wavelength band (220 nm) is due to the \( 1B_0 \) transition while the long wavelength band (260–290 nm) consists of the two overlapping transitions \( 1L_a \) and \( 1L_b \) with vectors almost perpendicular to each other. The \( 1L_a \) transition is sensitive to the polarity giving rise to a slight shift in absorbance spectrum. The \( 1L_a \) transition is believed to be the main contributor to the emission.

In aqueous solution tryptophan displays a wide, structureless fluorescence band with a maximum of about 350 nm and width of about 60 nm. It is worth noting that tryptophan fluorescence spectra measured under the same conditions but using different instruments may differ slightly in position of the maximum (348–353 nm), width and shape because of the differences in spectral calibration. Unfortunately, at present there are no generally accepted standards for the spectral calibration of instruments in the near-ultraviolet region. Because excitation leads to a substantial increase in the dipolar moment (about 4 D), shifts in the emission are much stronger. This shift is caused by the orientational relaxation processes involving the dipole of the chromophore and solvent dipoles. This sensitivity of tryptophan emission to polarity and mobility of environment makes tryptophan fluorescence an important tool in studies of protein structure and dynamics.

The absolute quantum yield of tryptophan in an aqueous environment was reported to be 0.13\(^{13}\). In most cases, however, a knowledge of the absolute value is not necessary and relative quantum yield is used instead. Tryptophan fluorescence is susceptible to the quenching by water which occurs with high activation energy (11–12 kcal mol\(^{-1}\))\(^{14,15}\). This leads to the frequently observed decreases in quantum yield upon denaturation when tryptophan becomes exposed to an aqueous environment. However, there are numerous exceptions to this rule because tryptophan fluorescence can also be quenched in a protein’s native state.

Almost all polar protein groups can quench tryptophan fluorescence, to some extent\(^{14,16–21}\). Possible nonradiative processes include photoionization, intersystem crossing, exciplex formation, and excited state proton and excited state electron transfer. Aspartic and glutamic acid residues are effective dynamic quenchers in their neutral, but not charged, forms. Lysine and arginine are also dynamic quenchers, but are more effective when charged. Histidine at low pH appears to quench by formation of a stacking complex with the indole ring. The nonprotonated histidine is also able to quench tryptophan fluorescence, although with much-reduced efficiency. Disulfide is one of the strongest quenchers of tryptophan fluorescence, although single cysteine can be an effective quencher too. In addition, amide and peptide groups were shown to act as dynamic quenchers. In heme-containing proteins, long-range energy transfer quenching is important due to the spectral overlap.
of tryptophan emission and heme absorbance. While such effects complicate the analysis of protein fluorescence, they can also be used to extract valuable structural information. For example, in membrane-bound cytochrome b₅, heme quenching of Trp-109 was used to estimate the distribution of distances between two protein domains.\(^{22}\)

Tryptophan appears to be uniquely sensitive to quenching by a variety of substances, such as oxygen, iodide, bromide, acrylamide, succinimide, hydrogen peroxide, dichloroacetamide, pyridinium hydrochloride, NO₃⁻, Cs²⁺, Cu²⁺, Pb²⁺, Cd²⁺ and Mn²⁺.\(^{14,16,23}\) This sensitivity to quenchers allows determination of the accessibility of the tryptophan residues in proteins by quenching measurements.

The fluorescence decay of tryptophan does not follow a single exponential. Szabo and Rayner\(^{24}\) had reported two decay times of 0.5 and 3.1 ns for tryptophan zwitterion in an aqueous environment at room temperature. The short-lived component has a blue-shifted spectrum. The heterogeneity of decay of tryptophan derivatives in fast-relaxing environments is attributed to the side chain rotamers. Decay becomes even more complex when solvent relaxation occurs on a nanosecond timescale (see section 2.3).

The existence of two overlapping transitions and energy transfer occurring predominantly from \(^1\)L₉ to \(^1\)L₈ complicates the appearance of the excitation polarization spectrum of tryptophan. In their classic work, Valeur and Weber\(^{25}\) have resolved two transitions in the excitation spectrum of indole and tryptophan in frozen propylene glycol using polarization data. The limiting anisotropy of tryptophan depends on the excitation wavelength and is about 0.3 at 300 nm, and 0.2 at 270 nm. The spectral region in-between has several sharp bands, which are expected to shift depending on the solvent conditions, making the region from 280 to 300 nm difficult to use for polarization measurements.

An important emerging field in protein fluorescence is related to the use of spectrally enhanced protein mutants.\(^{26}\) This approach takes advantage of tryptophan analogs with different photophysical properties incorporated as intrinsic fluorophores either by chemical synthesis or, biosynthetically, using tryptophan auxotroph Escherichia coli strains.\(^{27,28}\) Three analogs are suggested to be most useful for studies of protein–protein and protein–nucleic acid interactions: 5-hydroxytryptophan (2), 4-fluorotryptophan (3) and 7-azatryptophan (4). 5-Hydroxytryptophan absorbance has a long wavelength shoulder going as far as 320 nm, allowing this fluorophore to be selectively excited in the presence of multiple normal tryptophan residues. In addition, when excited in this region 5-hydroxytryptophan has a high limiting anisotropy, making it useful for polarization studies. 4-Fluorotryptophan is nonfluorescent, making a “silent” analog. It also has been used in nonfluorescence experiments because of its altered ground state dipole. 7-Azatryptophan has a dramatic change in quantum yield upon exposure to water, making it potentially useful in protein folding experiments.

### 2.1.2 Other Natural Fluorophores and Fluorescence Labels

A variety of biological molecules contain naturally occurring or intrinsic fluorophores. Tryptophan is the most highly fluorescent amino acid in proteins (see sections 2.1.1 and 2.2). It is so widely used that the term “natural protein fluorescence” is almost always associated with tryptophan fluorescence. The second most fluorescent amino acid is tyrosine, but its application is mostly limited to tryptophan-free proteins. Fluorescence of phenylalanine is weak and almost never used in protein studies. Another class of natural fluorophores consists of cofactors, NADH (reduced β-nicotinamide adenine dinucleotide) being the most prominent.

The fluorescence properties of NADH have been the subject of multiple studies.\(^{29–31}\) In aqueous solution the quantum yield of fluorescence is low and the average lifetime is in the subnanosecond range due to stacked conformation of the molecule. Binding to liver alcohol dehydrogenase leads to a blue-shift in absorbance and fluorescence and an increase in quantum yield (see section 3.2). This effect is enhanced by formation of a ternary complex with the substrate analog isobutyramide. The lifetime distribution for NADH shifts into a nanosecond range and undergoes a complex change in binary and ternary complex, indicating the existence of an excited state reaction.\(^{31}\)

The fluorescence properties of natural chromophores are frequently inadequate for certain studies. In these cases fluorophores foreign to the system under study but displaying improved spectral properties are chosen. These extrinsic fluorophores when covalently linked to a protein (usually at a cysteine or lysine side chain) are called fluorescence labels. Modern labeling procedures in combination with mutagenesis allow labels to be introduced selectively at a specific location in a protein. The Handbook of Fluorescent Probes and Research Chemicals\(^{(32)}\) provides an excellent source of information on various dyes and labeling procedures.
In an ingenious example of the use of a fluorescence label, the fluorescence properties of 6-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)aminohexonic acid (NBD) were utilized to determine the environment of the nascent chain in the translocon complex (Figure 1). Emission of NBD is very sensitive to the properties of its environment: moving from an aqueous to apolar environment increases the lifetime and the quantum yield and causes blue-shift of emission. Nascent chains, however, cannot be labeled selectively in the presence of ribosomes and endoplasmic reticulum-membrane proteins. Site-specific positioning of the probes in the nascent polypeptides can only be achieved by using aminoacyl-tRNA analogs that incorporate amino acids labeled with suitable probes into the chain as it is being synthesized. Johnson et al. devised a method for preparing analogs in which probes are covalently attached to the side chain of lysine in Lys-tRNA. The validity of the approach was demonstrated by showing that the modified lysines were incorporated successfully into proteins in vitro. Since different models of translocon organization differ primarily in the exposure of the nascent chain to the cytoplasm, they could be tested directly by determining whether fluorescent dyes in the nascent chains of membrane-bound ribosomes were accessible to water-soluble quenchers in the cytoplasm. NBD dyes located at different positions along the nascent chain pathway in free ribosomes were each found to have very short fluorescence lifetimes (less than a nanosecond) and to be quenched when iodide ions were added to the solvent. Thus, the nascent chain is in an aqueous environment and exposed to the cytoplasm when bound to a free ribosome. But when iodide ions were added to membrane-bound samples of the same ribosome–nascent-chain complexes, the Stern–Volmer constant for fluorescence quenching was reduced by an order of magnitude. This observation led to the conclusion that, in early stages of translocation, the nascent chain is tightly surrounded by the ribosome and membrane components of the endoplasmic reticulum.

2.2 Spectral Classes of Tryptophan Residues

The position of the maximum of the fluorescence spectrum of tryptophan residues in proteins varies from 307 to 353 nm. According to the model of discrete states of Burstein et al., there are five most probable spectral forms of tryptophan residues (Figure 2). Formation of various exciplexes (complexes in the excited state) and subsequent dipole relaxation is believed to cause the red-shift of emission.

Spectral form A corresponds to the emission of the unperturbed indole chromophore in the extremely nonpolar environment inside the protein globule. Such emission in its pure form was found only in azurin, however the class A spectrum contributes to the total spectra of a few other proteins. Azurin, a small globular metal-binding protein, contains a single tryptophan residue that displays a rather unusual fluorescence spectrum. It is extremely blue-shifted, with a main maximum of about 307 nm, and it possesses a distinct vibrational structure. The emission from the \(1\) state is assumed to contribute significantly in the spectrum, giving rise to mirror symmetry of emission and absorbance.

---

**Figure 1** Example of the experimental system requiring the use of fluorescence labels in protein studies. Neither intrinsic fluorescence nor conventional labeling can specifically probe the environment of the nascent chain (solid line) in the presence of ribosome–translocon complex (large ovals). To overcome this limitation Crowley et al. have developed a way to biosynthetically incorporate NBD-labeled (small ovals) lysine residues in the nascent chain. Fluorescence of NBD dye is sensitive to the polarity of its environment and to addition of water-soluble quenchers, such as iodide. Combination of steady-state and phase-modulation measurements allowed differentiation between various possibilities of organization of the translocon complex. (Reproduced by permission of Cell Press.)

**Figure 2** Normalized fluorescence spectra of tryptophan residues belonging to five spectral classes A, S, I, II and III according to Burstein. Extreme variability of the emission of the indole fluorophore, depending on polarity and mobility of its environment, makes tryptophan fluorescence a sensitive tool in protein analysis. (Reproduced by permission of ONTI NCBI.)
Freezing an azurin solution does not change the position of its fluorescence spectrum.

Spectral form S corresponds to the emission of the indole chromophore located in the relatively nonpolar environment inside the protein globule and forming a 1:1 exciplex with some polar protein group. The S spectrum has a maximum at 316–317 nm and shoulders at 305–307 nm and 320–330 nm. It is of interest that a pure S spectrum has never been reported, but is always accompanied in proteins by a contribution from the class I spectrum (see below), which corresponds to a 2:1 exciplex. For example, types S and I contribute almost equally to emission of L-asparaginase. It is assumed that during the excitation lifetime the 2:1 exciplex with two neighboring polar protein groups occurs in the native proteins, but are typical for unfolded environments.

Most proteins, however, exhibit spectra that contain contributions from different classes. To resolve those contributions a fitting procedure was designed based on a parameterized description of fluorescence spectra. The heart of this analysis lies approximation of emission spectra with the log-normal distribution usually expressed on the scale of wavenumbers, \( v \), as shown in Equations (7) and (8):

\[
I(v) = I_{\text{max}} \exp \left( -\frac{\ln^2}{\ln^2 \rho} \ln \frac{a - v}{a - v_{\text{max}}} \right) \quad \text{for } v < a \tag{7}
\]
\[
I(v) = 0 \quad \text{for } v \geq a \tag{8}
\]

where \( I_{\text{max}} \) is intensity at position of maximum, \( v_{\text{max}} \), and \( \rho = (v_{\text{max}} - v^-)/(v^+ - v_{\text{max}}) \) is spectral asymmetry. Parameter \( a = v_{\text{max}} + (v^+ - v^-)\rho/(\rho^2 - 1) \), where \( v^- \) and \( v^+ \) are the positions on the wings of the spectrum where intensity equals half of \( I_{\text{max}} \). The total of four fitting parameters \( (I_{\text{max}}, v_{\text{max}}, v^-, v^+) \) per spectrum is adequate to get a unique solution, but to resolve two or more spectral components additional constraining factors are required. They are obtained from the empirical observation that width and position of the maximum of tryptophan derivatives in isotropic media are related as shown in Equations (9) and (10):

\[
v^+ = 0.8308v_{\text{max}} + 7071 \text{ cm}^{-1} \tag{9}
\]
\[
v^- = 1.1768v_{\text{max}} + 7681 \text{ cm}^{-1} \tag{10}
\]

An advanced version also utilizes spectra collected at different concentrations of quenchers to increase reliability and robustness of fit.

In a simplified version of the analysis, the spectrum is fitted to a single log-normal distribution (often on a wavelength scale) to recover full width at half-height, \( \gamma \), and position of maximum, \( \lambda_{\text{max}} \). If the point on a spectral width vs position plot appears above the standard line for tryptophan in model isotropic media, several spectral classes are present. For example, a conformational change in bee venom peptide melittin can be followed by position-width analysis of steady-state spectra of Trp-19 (Figure 3). At low ionic strength melittin exists as a mainly unstructured monomer with highly exposed tryptophan (spectral class III). Additions of salt induce a monomer–tetramer transition, resulting in the removal of the tryptophan side chain from the aqueous phase (spectral class I). Intermediate states have significantly broadened spectra and follow theoretically
predicted semi-arc patterns. \(^{(37)}\) Several advantages of position–width analysis over simple analysis of \(\lambda_{\text{max}}\) are immediately obvious. First, it is clear that spectral class II is not involved in the transition, because the spectra in the mid-transition are too broad, although they have the same maximum as II. Second, \(\lambda_{\text{max}}\) is not changed appreciably in the last stages of transition, and completion of conformational change is best judged by the narrowing of the spectral width. It should be emphasized, however, that despite its sensitivity the analysis of spectral position cannot be used to quantitate the conformational change or ligand binding, because \(\lambda_{\text{max}}\) is not a linear response function (see section 3.2).

To calculate the thermodynamic parameters one should use one of the linear response spectroscopic functions as the observable, e.g. the intensity at any constant wavelength.

**2.3 Protein Dynamics and Heterogeneity of Fluorescence Decay**

It has long been noted that even for single tryptophan-containing proteins, fluorescence decay does not follow simple exponential kinetics. \(^{(43)}\) Due to the nature of the lifetime analysis certain assumptions have to be made, which usually means that complex decay is assumed to be described by a number of exponential components. As instruments become more sophisticated, more components have been reported and even the distributions of lifetimes have been utilized to fit the data. \(^{(44–47)}\)

Regardless of the mode of analysis (discrete exponentials or distributions), the main empirical result is that it takes several parameters to describe fluorescence decay. Exponentials, however, do not form an orthogonal system of functions and multiple solutions can exist which fit the same data equally well. Therefore, one should use the term multi-exponential decay with caution, keeping in mind that the exact nature of nonexponentiality might not be known, and that recovered components may or may not have a physical meaning.

Interpretations of complex decay of tryptophan fluorescence fall into two main categories: ground state heterogeneity (e.g. rotamer model) and excited state reaction (e.g. relaxation model). Based mainly on model studies done with tryptophan and tyrosine derivatives, several groups have suggested that different rotameric forms are responsible for nonexponential decay. \(^{(24,48,49)}\)

In recent years there has been a breakthrough in understanding the mechanisms governing the decay of rotamers of restricted indole derivatives. \(^{(20,50,51)}\) However, those model studies were carried out in isotropic fast-relaxing media. Proteins, in contrast, are heterogeneous systems with a hierarchy of internal motions that cover a wide range of correlation times, including the nanosecond time window of fluorescence. On the other hand, the excited state reaction approach relies on protein dynamics to convert electronically excited indole into other spectroscopic species. More specifically, the relaxation model assumes that such reaction involves reorientation of polar groups surrounding tryptophan in a protein. \(^{(52–54)}\) Neither of the models has been unequivocally proven for any specific protein.

Recently it has been suggested that excitational dependence can be used as a criterion to distinguish between alternative mechanisms causing deviations from exponential decay in proteins. \(^{(55)}\) This approach takes advantage of considerations developed to explain inhomogeneous broadening of the electronic spectra of dye molecules caused by the distribution in configurational energy in solvate. \(^{(56–58)}\) Such systems are characterized by the following features: (1) decay is nonexponential, (2) decay depends on the excitation wavelength, \(\lambda_{\text{exc}}\), and becomes faster at longer \(\lambda_{\text{exc}}\) (red-edge effect), and (3) in extreme cases a rising component in intensity (negative pre-exponential) is observed at the longer emission wavelength.

An abbreviated summary of these features for fluorescence decay in simple model systems and in proteins...
Table 1 Summary of heterogeneity of fluorescence decay of indole fluorophore in model media and in proteins

is presented in Table 1 (Ladokhin, unpublished). Slowing of dipolar relaxation by additions of glycerol leads to progressive heterogeneity and excitational dependence in fluorescence decay of the indole molecule, which obviously lacks rotameric forms. Note that deviation from exponentiality starts at low glycerol concentrations, before the negative pre-exponential could be observed under commonly used instrumental conditions (the width of the excitation pulse was 60 ps). As described above (see section 2.1.1), tryptophan zwitterion in aqueous solution shows a double exponential decay due to rotameric forms. In this case, however, the decay is independent of the excitation wavelength. When a tryptophan molecule is placed under conditions of mild viscosity, decay becomes more complex, and in this case excitational dependence can be detected. In proteins the excitation dependence can be small or significant and the negative exponential normally is not observed unless four exponential components are used in the analysis, and then only for a few proteins. Melittin in methanol, when it is helical and monomeric, constitutes an exception when a negative pre-exponential is observed with one of the three components. This overall behavior of proteins is consistent with contributions from both ground state heterogeneity and excited state reactions.

The model studies presented above indicate the importance of protein dynamics for interpretation of fluorescence decay in proteins. This is also true for other fluorescence parameters, such as dynamic depolarization, biomolecular quenching rate, temperature-induced quenching in the native state, red-edge excitation shift, distribution of distances calculated in energy transfer experiments, etc. In a sense all protein fluorescence spectroscopy is influenced by the dynamic nature of protein. Further understanding of this link will allow one to solve the reverse task and to determine dynamic parameters of protein structure from its fluorescence.

3 FLUORESCENCE STUDIES OF PROTEIN CONFORMATION AND INTERACTIONS

3.1 Protein Folding

Fluorescence spectroscopy plays a major role in protein folding studies. For example, the fluorescence increase of 8-anilino-1-naphthalensulfonic acid was used to identify the molten globule state during refolding of various proteins, and intrinsic fluorescence, along with other methods, was utilized to provide evidence for a two-state transition in chymotrypsin inhibitor. A variety of fluorescence observables can be used to follow denaturation or renaturation of the protein native structure induced by changes in temperature, pH or additions of solutes. One such example has already been discussed in previous sections – changes in the emission bandshape following tetramerization of melittin was presented in Figure 3 (see section 2.2). Another example is the change in emission maximum and polarization of tryptophan fluorescence of apohorseradish peroxidase upon addition of a denaturing agent, guanidinium chloride. Unfolding of this protein results in increased exposure of a single tryptophan residue to aqueous environment revealed by the fluorescence red-shift (Figure 4). Increased mobility of the tryptophan due to the loss of native packing contacts upon denaturation results in the parallel loss of emission polarization. Note that an excitation wavelength of 300 nm was used for polarization measurements to avoid strong depolarization (insert, Figure 4), due to overlapping transitions at the shorter wavelengths (see section 2.1.1). In addition to emission maximum and polarization, a number of other parameters (e.g. intensity, lifetime distribution, Stern–Volmer constant, efficiency of the radiationless energy transfer) can be utilized in steady-state protein folding studies. But the advantages of fluorescence studies of folding are demonstrated most vividly, perhaps, with kinetic measurements.
Among the spectroscopic methods used in combination with stopped-flow mixing, fluorescence is probably the simplest, yet most sensitive and widely employed. Recent years have been marked by considerable advances in both mixing techniques and kinetic acquisition of spectroscopic data. Application of advanced continuous-flow mixing to follow the energy transfer from tryptophan and tyrosines to heme in cytochrome c has allowed probing of the barrier-free submillisecond transition between the initially collapsed state and the native state. Using a combination of both continuous-flow microsecond mixing and conventional stopped-flow mixing, Shastry et al.\(^\text{(64)}\) demonstrated how continuous kinetic data from 50\(\mu\)s to \(>10\) s after initiation of the folding event can be obtained (Figure 5). Ramsay et al.\(^\text{(65,66)}\) have developed a fluorimeter/CD photometer hybrid allowing global changes in secondary structure and local changes in the tryptophan environment to be determined simultaneously for the same sample.

Beechem et al.\(^\text{(67–69)}\) have pioneered the development of another important technical advance in spectroscopic analysis of fast kinetic effects by combining the advantages of time-resolved spectroscopy with kinetic stopped-flow measurements. This double-kinetics technique achieves simultaneous measurement of changes in fluorescence on both the picosecond/nanosecond and millisecond timescale. After initiation of folding the decay of tryptophan anisotropy is measured in millisecond intervals of time, thus allowing the determination of tryptophan rotation mobility “in real time” during protein refolding. This allows ascertaining the timescale associated with tryptophan “packing” into intermediate structures and eventually into the final native state. Such experiments can also follow the changes in lifetime due to different fluorescence quenching in the folded and unfolded state. If two fluorophores capable of making a donor–acceptor pair are introduced, such studies can be used to determine the changes in distance between labeled sites on the millisecond timescale.

In addition to the water-soluble systems discussed above, fluorescence spectroscopy is now being employed to study folding of membrane proteins\(^\text{(70–74)}\) (see section 3.3).
3.2 Protein–Ligand Interactions

There are two principal possibilities that can be exploited to study protein–ligand interactions. The fluorescence of either the protein or the ligand can change upon binding. These two situations require somewhat different data analysis procedures. When changes in the fluorescence of a protein are observed, the fluorophore may be one or more of the intrinsic tryptophan residues, or it may be the covalently attached or tightly bound fluorophore.

Tryptophan is a relatively sensitive fluorophore. Its spectrum can vary more than 40 nm (see section 2.2) and its quantum yield in proteins and peptides ranges from virtually zero to almost 0.5. The latter change is usually accompanied by a corresponding variation in the excited state lifetime. The binding of a ligand to a protein may directly affect the fluorescence of a tryptophan residue by acting as a quencher (i.e. by a collisional or energy transfer mechanism) or by physically interacting with the fluorophore and thereby changing the polarity of its environment and/or its accessibility to solvent. Alternatively, a ligand may bind at a site remote from the tryptophan residue and act via a generalized mechanism by inducing protein conformational change, which alters the microenvironment of the tryptophan. Both direct and generalized effects may result either in enhancement or quenching of fluorescence and/or in shifts in the spectrum to the red or blue. If there are multiple tryptophan residues in a protein, this will make it difficult to assign any fluorescence changes to a specific residue. To overcome this limitation, structural studies are now being conducted on single tryptophan-containing mutants. However, for many other purposes, e.g. the thermodynamics of ligand binding, the presence of multiple fluorophores is a minor consideration. More important is the fact that the observable be a linear-response function.

3.2.1 Linear-response Spectroscopic Techniques

Consider the simple case of a two-state equilibrium (the general case is described by Toptygin and Brand(76)) that can be followed by a change in a certain spectroscopic parameter \( S \) that changes from a value \( S_{\text{min}} \) in the absence of binding to \( S_{\text{max}} \) when all of the molecules are bound. The fractional change in the spectroscopic parameter \( f_{\text{signal}} \), defined as \( f_{\text{signal}} = (S - S_{\text{min}})/(S_{\text{max}} - S_{\text{min}}) \), is often used to characterize the extent of completion of the binding reaction. The fraction of bound molecules \( f_{\text{bound}} = P_{\text{bound}}/P_{\text{total}} \) will coincide with \( f_{\text{signal}} \) only if \( S \) is a linear-response function. For that case, the signal observed can be represented as a linear combination of molar fractions of bound and free molecules weighted by their corresponding molar spectroscopic characteristics, \( S_{\text{bound}} \) and \( S_{\text{free}} \), as shown in Equation (11):

\[
\frac{S}{P_{\text{total}}} = f_{\text{bound}}S_{\text{bound}} + f_{\text{free}}S_{\text{free}}
\]

\[
= f_{\text{bound}}S_{\text{bound}} + (1 - f_{\text{bound}})S_{\text{free}} \tag{11}
\]

Not all spectroscopic data satisfy this equation. For example, the following spectroscopic parameters are not linear-response functions and therefore cannot be utilized for measurements of binding: position of maximum of the fluorescence spectrum and related parameters such as center of weight, center of the chord at any intensity level, or ratio of intensities on the wings; fluorescence polarization (or anisotropy); intensity at the maximum of the spectrum; the phase \( \phi \) and modulation \( m \) from frequency domain fluorimetry; fluorescence decay curve collected to a constant peak; and transmittance from spectrophotometric measurements. Parameters that are linear-response functions and that can be utilized for measurements of binding include the following: fluorescence quantum yield; steady-state intensity at a constant wavelength \( I_{\text{ss}} \); \( I_{\text{ss}} \cos \phi \) and \( I_{\text{ss}} \sin \phi \);(76) fluorescence decay curve collected to a constant time; vertical and horizontal components of fluorescence intensity (and of any other angle too); and absorbance from spectrophotometric measurements.

In addition to general rules that apply to all binding experiments, there are some peculiarities relevant to specific aspects of experimental schemes. For example, in membrane partitioning experiments there is an explicit assumption that \( S_{\text{bound}} \) does not depend on the completion of binding or on the number of bound molecules per lipid vesicle. However, in the case of fluorescence, the intensity can be a nonlinear function of bound molecules due to nonradiative energy homotransfer or other self-quenching mechanisms. This possibility is often overlooked during the analysis of complex membrane partitioning. Various spectroscopic and nonspectroscopic methods to quantitate binding to membranes are discussed elsewhere.(77)

Toptygin and Brand(76) have developed special software to fit multiple families of titration data obtained with any of the linear-response spectroscopic techniques. The SPECTRABIND program uses model equilibrium equations as constraints to determine the basic components associated with the actual chemical species and their concentrations. A statistical test is used to discriminate between adequate and inadequate models, the decision being independent of any knowledge and/or assumptions about the spectroscopic characteristics of chemical species. This approach is aimed at systems involving multiple interactions, where the changes in spectroscopic signal cannot be attributed to a single interaction. An example
of the application of SPECTRABIND to the interaction of horse liver alcohol dehydrogenase with NADH and isobutyramide is given in Figure 6. Fluorescence spectra of NADH in various binary and ternary complexes recovered from the same titration data sets using two different binding models are presented. Both models assume that the two binding sites (one on each of the identical subunits of the protein dimer) are identical and independent in terms of association constants. Figure 6(a) contains results obtained under the additional generic assumption that binding to the two sites is also spectroscopically independent. The three essential spectroscopic species correspond to a free NADH (N), its binary complex with the protein subunit (SN), and its ternary complex with additional isobutyramide (SNI). Protein (S) and isobutyramide (I) by themselves produce negligible signal, while the background signal (B) contains a sharp peak of Raman scattering band of water. The model from Figure 6(b) does not assume spectroscopic independence of binding sites and contains multiple species of various combinations of the entire dimeric protein (P) with one or two NADH and isobutyramide molecules. The association constants for each binding step are also determined. This example illustrates the ability of the SPECTRABIND program to analyze complex binding equilibria.

The basic limitation of spectroscopic techniques for studying protein–ligand interactions is the necessity for a sufficiently strong change in some spectroscopic signal. The lack of an adequate signal can hinder rigorous quantitative determination of binding. To overcome this limitation in studies of nucleic acid-binding proteins, Jezewska et al. applied an inventive approach that takes advantage of the strong fluorescence of the reference ligand. An example of application of the Macromolecule Competition Titration method for binding of nonfluorescent single-stranded nucleic acid poly(dA) to DnaB helicase is presented in Figure 7. The observed fluorescence signal was due to the poly(dεA), an etheno derivative of poly(dA), used as a reference. This method allows the determination of absolute average binding density and construction of a model-independent true binding isotherm.

3.3 Membrane Proteins and Peptides

Determination of membrane organization and dynamics is one of the most challenging problems of structural biology because many methods (even of low resolution) developed for water-soluble systems are not directly applicable to membranes. For example, while the position of the fluorescence spectrum of tryptophan in a globular protein indicates a degree of exposure to the aqueous phase, it will not be sensitive to exposure to the...
lipid phase in a membrane-bound protein. Therefore, new approaches should be developed for structural studies in membranes. The depth-dependent fluorescence quenching technique is a useful tool to explore the structure of membrane proteins and peptides along the depth coordinate.\(^\text{74,80–85}\) To achieve this objective it utilizes lipids with bromine atoms (Figure 8) or spin labels selectively attached to certain positions along acyl chains. This is a dynamic quenching resulting in decrease of both intensity and lifetime.\(^\text{42,71}\)

In a depth-dependent fluorescence quenching experiment one normally determines the fluorescence intensity,\( F \), of a probe as a function of the known depth of the quencher,\( h \). Data are usually normalized to the intensity in the absence of quenching,\( F_0 \). Distribution analysis is one of the methods that can be used to quantitate the quenching in order to extract information on membrane penetration. It assumes that the quenching profile can be approximated by a symmetrical double-Gaussian function, which accounts for \( \text{cis-} \) and \( \text{trans-leaflet} \) quenching,\(^\text{70,87}\) as shown in Equations (12) and (13):

\[
\ln \frac{F_0}{F(h)} = G(h, \sigma, S) + G(-h, \sigma, S) \quad (12)
\]

\[
G(h, \sigma, S) = \frac{S}{\sigma \sqrt{2\pi}} \exp \left(-\frac{(h-h_\text{m})^2}{2\sigma^2}\right) \quad (13)
\]

where\( h_\text{m}, \sigma \) and\( S \) are the three fitting parameters: mean position, dispersion and area, respectively.

The position of the maximum represents the most probable transverse location of the fluorophore, while dispersion arises from the several broadening terms, such as finite size of the probe and the quencher and fluctuational distribution of their depth due to thermal motion. Multiple conformations will result in additional broadening of the profile. Equation (14) shows that the area under the quenching profile is a product of the inherent quenching constant,\( \gamma \), determined by the nature of the quenching mechanism, excited state lifetime in the absence of quenching,\( \tau \), the degree to which the probe is exposed to a lipid phase,\( w \), and the concentration of the quencher,\( C \):

\[
S = \gamma w \tau C \quad (14)
\]

Variation of exposure arising from the shielding of tryptophan side chains by the protein moiety provides important structural information on protein conformation.

---

**Figure 7** Example of protein–ligand interactions followed by means of fluorescence spectroscopy. The exceptional sensitivity of fluorescence is utilized in a variety of binding studies using one of the linear-response spectroscopic functions (e.g. intensity at a constant wavelength). Normally the fluorescence of the protein or ligand is altered as a result of the interaction. Jezewska and Bujalowski\(^\text{79}\) have introduced a Macromolecule Competition Titration Method to study those interactions that do not directly result in such changes of fluorescence. Instead, the fluorescence of the reference ligand (an etheno derivative of a polynucleotide in this case) is measured in the presence of various concentrations of the ligand under study (nonlabeled polynucleotide). Fluorescence increase, plotted as a function of the protein concentration (DnaB helicase, symbols), is fitted using a binding model (solid lines) to calculate various parameters. Binding constants, parameters of cooperativity of binding and stoichiometry can be studied by fluorescence titration methods. (Reproduced by permission of the American Chemical Society.)

**Figure 8** Set of bromolipids utilized to examine membrane penetration of proteins and peptides. Selective labeling of different positions along one of the acyl chains with bromine atoms, which are capable of quenching fluorescence via dynamic collisional mechanism,\(^\text{42}\) allows the transverse position of the fluorophore to be determined. Two bromine atoms (large spheres) per lipid are attached in neighboring positions. This “molecular ruler” has been calibrated in an independent diffraction experiment yielding the distances (given in angstroms) from bromines to the bilayer center.\(^\text{86}\) Depth-dependent fluorescence quenching profiles measured utilizing bromolipids can be evaluated with the help of distribution analysis\(^\text{70,87,88}\) (see Figure 9 for examples) to obtain a variety of structural information.
in the lipid bilayer. Equation (15) shows that the relative exposure, $\Omega$, can be estimated as the ratio of absolute exposures of tryptophan residue in a protein, $w_p$, to that in a model compound (e.g. tryptophan octyl ester$^{42,88}$), $w_M$:

$$\Omega = \frac{w_p}{w_M} = \frac{S_P TM}{S_MT_P} \approx \frac{S_P Q_M}{S_M Q_P}$$  \hspace{1cm} (15)$$

If the lifetime measurements are not available, the ratio of $\tau$ values can be approximated by the ratio of quantum yields, $Q$, of a protein and a model compound in a nonquenching lipid membrane.

Application of the distribution analysis technique to a mutant cytochrome $b_5$ and to a model membrane-spanning peptide are presented in Figure 9. A single fluorophore of the membrane-binding peptide of cytochrome $b_5$ mutant, Trp-108, was found to be located close to the membrane interphase and its distribution along the depth coordinate is relatively narrow, suggesting the lack of conformational freedom.$^{70,87}$ The relative exposure of Trp-108 to lipid phase equals 0.66, as compared to tryptophan octyl ester. A single tryptophan in a membrane-spanning peptide is located deep in the hydrophobic core of the bilayer. For this peptide, the use of a double-Gaussian fitting function was especially important due to strong trans-leaflet quenching. Thus for this peptide the unimodal distribution of transverse position (Figure 9) differs from that of a quenching profile.

It has been demonstrated that all three parameters – average depth of the tryptophan, the width of its transverse distribution and the degree of its exposure to the lipid phase – are different in various proteins and peptides. Studies of melittin and various mutants of cytochrome $b_5$ and of outer membrane protein A indicate that these parameters can be altered by temperature-induced conformational change or during the kinetic insertion and folding.$^{70–73,88}$

Another important aspect of the structural characterization of membrane proteins and peptides is determination of their topology. The critical issue is: Does a particular peptide equilibrate freely across the bilayer, form a stable transmembrane structure, or remain only on one surface? Recently Wimley and White$^{91}$ have developed a method that uses fluorescence quenching arising from resonance energy transfer for determining the topology of the tryptophan residues of peptides partitioned into phospholipid bilayer vesicles. This is accomplished through the use of a novel lyso-phospholipid quencher, lyso-methylcoumarin (LysoMC). Methylcoumarin quenches the fluorescence of membrane-bound tryptophan by the long-range resonance energy transfer mechanism with an apparent Förster distance that is comparable to the thickness of the hydrocarbon core of a lipid bilayer ($\sim 25\text{ Å}$). Consequently, the methylcoumarin acceptor predominantly quenches tryptophans that reside in the same monolayer as the probe. The topology of a peptide’s tryptophan in membranes can be determined by comparing the quenching in symmetric and asymmetric LysoMC-labeled vesicles (Figure 10).

Both structural and thermodynamic studies on membrane proteins are clearly lagging behind those of their soluble counterparts. Only recently have the first basic principles of integral protein structure and stability begun to emerge.$^{77,92}$ The general reason for this is that the lipid bilayer membrane appears to be too large and
slow-tumbling for solution NMR studies and too “two-dimensional” for X-ray crystallography. These limitations hindering applicability of high-resolution structural techniques do not compromise in principle the application of fluorescence and other spectroscopic methods (e.g. EPR\(^{93}\)). Therefore, in addition to its traditional role as a technique sensing dynamic fluctuational aspects of protein structure and its kinetic metamorphoses, fluorescence spectroscopy is assuming a new role as a direct structural tool in studies of membrane proteins.

**ACKNOWLEDGMENTS**

I am very grateful to Drs L. Brand, W.M. Bujalowski, E.A. Burstein, A.E. Johnson, D. Toptygin, S.H. White and W.C. Wimley for providing me with the original figures from their publications, to Dr P.W. Holloway for creating an image of brominated lipids, and to Mr M.A. Myers for proofreading and editing the manuscript. During writing I was supported by grant GM-46823 (Prof S.H. White, PI) from the NIH. I would like to dedicate this contribution to Profs G. Weber, S.V. Konev, M. Kasha, L. Brand and E.A. Burstein who shaped my understanding of fluorescence phenomena by memorable conversations and by their groundbreaking research.

Infrared (IR) spectroscopy is one of the two forms of vibrational spectroscopy, the other being Raman spectroscopy. IR spectroscopy measures absorptions of vibrating molecules and yields information about molecular structures and structural interactions. The development of computerized Fourier transform infrared (FTIR) techniques has opened up new dimensions in biological IR spectroscopy owing to the increase in achievable signal-to-noise ratios, wavenumber accuracy, and data acquisition rates, and the ability to perform measurements with strongly absorbing samples. High-quality FTIR spectra can be obtained with relative ease and rapidly with very small amounts of sample in a variety of environments. Measurements of proteins in aqueous solution are almost routine now, and can be performed under equilibrium and nonequilibrium conditions. There are many IR absorption bands characteristic of peptide groups and amino acid side-chain groups from which information on protein structures can be obtained. The information provided by FTIR spectroscopy may be a global one or highly specific for a single vibrating chemical group. In some cases, the usefulness of the method is limited by difficulties in extracting the structural information contained in the IR absorption bands.

1 INTRODUCTION

Over the last few decades, IR spectroscopy has incorporated technological advances in physics, biochemistry, engineering, computer science, and molecular biology to become an invaluable tool in structural biology. FTIR spectroscopy now provides molecular information in systems ranging from small peptides and isolated enzymes...
to peptide–protein complexes and membrane proteins. The information can either be highly specific for a single vibrating group in an enzyme or it may report global changes, e.g. due to some experimental procedure. Furthermore, the process of obtaining structural information is not restricted to a static picture but can also be achieved in real time by applying time-resolved IR techniques. An important feature to that, the size of a protein or the nature of the environment does not limit the application of FTIR spectroscopy. Measurements can be performed in aqueous solution or organic solvents, in oriented films or dispersions, and in detergents or membrane-like environments. High-quality spectra can rapidly be acquired (seconds to minutes) and require only relatively small amounts of protein sample (as low as 10–100 µg). Advances in instrumentation and numerical data analysis today permit the quantification of protein secondary structures from IR spectra. One of the strengths of FTIR spectroscopy in this respect is the sensitivity to assess, in relative terms, the extent and nature of changes in secondary and tertiary structure of peptides and proteins. The effects of environmental factors, point mutations, or ligand binding on the structure of soluble proteins or enzymes can be examined with high sensitivity by using peptide backbone and side-chain IR bands as conformation-sensitive monitors. Changes in external factors (such as temperature) and data acquisition may be performed under computer control, thereby permitting the design of complex experiments using automatic scanning under highly reproducible conditions. In addition to the normal spectroscopic analysis, these types of experiments can also provide typical structural and standard thermodynamic parameters of proteins and enzymes.

FTIR spectroscopy has proven to be particularly valuable for studying membrane-associated peptides and proteins, since they are often difficult or impossible to investigate by other spectroscopic methods (e.g. owing to light scattering artifacts, solubility, and structural integrity). Beyond the ability to measure even large membrane proteins, IR spectroscopy also allows the study of lipids and membrane proteins simultaneously, without the use of marker molecules or extra probes. Moreover, polarized IR spectroscopy on oriented samples can provide structural information on the orientation of polypeptide chains within the membrane environment.

2 HISTORICAL OVERVIEW

IR spectroscopy is one of the earliest experimental methods recognized as potentially useful in providing information on structural features of peptides and proteins. As early as 1950 it was demonstrated that a strong correlation exists between the position of certain bands in IR spectra of homopolypeptides and their secondary structure.¹ Later, these experimental observations were refined by making detailed vibrational analyses of these structure-sensitive amide bands in order to establish a correlation between the frequencies of these bands and the type of secondary structure, such as purely α-helical or purely β-sheet structures.²,³ Nine such IR bands exist, which are assigned as amide A, amide B and amides I–VII, in order of decreasing frequency³,⁴ (Table 1).

Of all the amide bands, the most intense and most useful for the analysis of the secondary structure of proteins was found to be the amide I band, which occurs in the region 1600–1700 cm⁻¹. In contrast to the other amide vibrations, this band reflects an almost pure vibrational character, since it consists mainly of the carbonyl stretching vibration mode of the amide group. Figure 1(a) and (b) illustrates the different IR spectroscopic characteristics of the amide I band for two proteins fundamentally different in their secondary structure. The α-helically structured myoglobin shows a relatively sharp band centered at 1654 cm⁻¹ (a), whereas the antiparallel β-sheet structured concanavalin A displays an asymmetrically shaped amide I band with a maximum at 1635 cm⁻¹ and a weaker feature at 1694 cm⁻¹ (b).

Despite the well-recognized potential of the amide I band for conformational studies, interest in the IR spectroscopy of proteins remained limited for nearly three decades. Experimental conditions made it difficult to obtain reproducible spectra and to extract the structural information encoded in the IR bands. Major drawbacks that prevented widespread use of IR spectroscopy in the past were (i) the poor sensitivity and reproducibility of the classical dispersive IR spectrometers, which recorded spectra with low signal-to-noise ratio and low

been developed, each of them with certain weaknesses. Mathematical manipulation of the experimental data have the secondary structural composition of a protein by structure.

and quantified in more general terms of secondary and individual band components cannot easily be classified creates at the same time the difficulty that these individually high conformational sensitivity of these amide modes as being specific for each protein, but it also creates at the same time the difficulty that these individual band components cannot easily be classified and quantified in more general terms of secondary structure. In the last decade, different methods for determining the secondary structural composition of a protein by mathematical manipulation of the experimental data have been developed, each of them with certain weaknesses as described later in this article. In contrast to these indirect methods, a new, different, and very promising direct approach has been applied, which is based on the introduction of isotopic labeling of specific sites of the polypeptide chain. This allows FTIR spectroscopy to locate a particular secondary structure within the polypeptide chain and helps in analyzing conformational changes that originate exclusively from the labeled site. Since most of the IR labels have no structural consequences [similar to 13C-labeling experiments in nuclear magnetic resonance (NMR) spectroscopy] and isotopic replacement is relatively easily achieved by chemical synthesis of peptides and is biosynthetically feasible for proteins, the behavior of single amino acids or even atoms can be monitored within intact peptides or proteins. This information can be obtained in real time by applying different time-resolved FTIR techniques, which closes the gap between this methodology and visible and fluorescence spectroscopy.

3 INSTRUMENTAL TECHNIQUES AND SAMPLE PROCEDURES

3.1 General Considerations

Water (as one of the strongest IR-absorbing molecules) restricts the measurement of IR bands of molecules in biological water-containing systems if they occur in the range between 1600–1700 and 3100–3700 cm⁻¹ where water shows the strongest IR bands. Most of the early experiments were therefore limited to sample preparations in which the water was partially reduced or completely removed. Samples were prepared as dehydrated protein films deposited on IR-transparent substrates or as solid protein powders ground and pressed into potassium bromide pellets. These experiments should be regarded as good preliminary tests, but were of only limited relevance due to the nonphysiological nature of the measurements. Today’s sample preparations aim for the measurement of molecules in buffer solutions, which is permitted by the described inherent advantages of FTIR spectroscopy.

To record a spectrum of a sample in H₂O buffer solution, very short pathlength cells of 3–8µm are required, to prevent total IR absorption in the spectral regions of the water. According to the Lambert–Beer law, such short pathlengths limit the intensities of the IR bands and the signal-to-noise ratio at a given sample concentration. Consequently, relatively high sample concentrations (>10 mg mL⁻¹) are required for the measurement. To obtain the spectrum of a sample, digital subtraction of solvent/buffer absorptions from the spectrum of the sample is required. For appropriate subtraction, the spectrum of the solvent/buffer should be recorded under conditions (such as temperature, ionic strength, pH, number of scans, resolution, etc.) identical with those of the sample spectrum. In practice, identical physico-chemical parameters are very important for this procedure since variations will certainly cause changes to spectral features of the H₂O bands, preventing an ideal subtraction of the spectral buffer contributions.
Figure 2 (a) IR spectra of ribonuclease (RNase) T1 in H$_2$O buffer at a protein concentration of 28 mg mL$^{-1}$ (dashed line) and 7 mg mL$^{-1}$ (dotted line), together with the buffer spectrum (solid line). (b) IR spectra of RNase T1 after subtraction of the buffer spectrum.

For instance, the temperatures of the sample in aqueous solution and the solvent should coincide within 0.1 °C in order to avoid artifacts caused by temperature differences.

Figure 2(a) shows IR spectra of the enzyme RNase T1 in H$_2$O buffer at two different concentrations. For these transmission measurements, a micro drop of 2 µL of the enzyme solution (7 or 28 mg mL$^{-1}$) was placed between a pair of calcium fluoride (CaF$_2$) windows separated by a pathlength of 8 µm. The solvent spectrum (Figure 2a, solid line) was measured in an optimally matched second cell of slightly reduced pathlength, which takes into account the slightly lower water concentration in the protein sample measured. Among the IR window materials available for experiments in solution, CaF$_2$ is the most common because (i) it has a low refractive index which is similar to that of water (high light throughput, low tendency for interference fringe pattern in the spectra); (ii) it is relatively rugged; and (iii) it is transparent to IR light (>1000 cm$^{-1}$) as far as the ultraviolet (UV) region of the spectrum. Barium fluoride (BaF$_2$), a similar window material, has a lower spectral cutoff than CaF$_2$ (at ~800 cm$^{-1}$), enabling additional IR spectral bands to be observed, but it is less rugged than CaF$_2$ and significantly more soluble in aqueous solution. Others [such as ZnSe, thallium iodide (KRS-5), AgCl, or Irtran] are characterized by unfortunately high refractive indices, which results in major reflection losses and persistent fringing in the spectra.

Although CaF$_2$ is the most suitable window material for protein measurements, it is not an ideal window material for long-term measurements of calcium-binding proteins. The solubility of CaF$_2$ in water is very low, but possible contamination of the sample by dissolution of Ca$^{2+}$ from the CaF$_2$ window cannot completely be excluded. In direct consequence, the Ca$^{2+}$-free form of a sample may not persist during the collection of spectra over longer timescales. Nevertheless, flow-through demountable cells with Luer-lock fittings, CaF$_2$ windows and spacers covering pathlengths from 6 to 200 µm are often used for protein measurements. These cells are available from virtually any IR accessories supplier, but reveal some disadvantages in practice such as being difficult to clean, accidental injection of gas bubbles and the application of high pressure in the case of short pathlength cells.

To circumvent these problems, our design of a custom-made IR cell consists of a flat cover disk (w$_1$, typically made of CaF$_2$) and a second disk of the same material (w$_2$), with the center hollowed out to form a recessed parallel surface surrounded by a groove (see Figure 3). The groove (gr) prevents direct contact of the sample with the outer part of the disk. Pressing the cover disk (w$_1$) on to the sample disk (w$_2$) is sufficient to prevent the evaporation of water for many hours at room temperature and seals the cell. Two spacer discs (g$_1$ and g$_2$) e.g. made of lead or graphite are used as gaskets to fit the windows into the base mounting (h$_2$), which is then sealed with the lid mounting (h$_1$). For measurements at higher temperatures and/or for long-term experiments, the sealing surface of the disks is lubricated with mineral oil dissolved in a volatile organic solvent prior to filling and assembling the cell. This prevents both evaporation of the solvent (e.g. water) at high temperatures (e.g. 95°C), for up to several weeks, or changes of the isotope content when working with deuterium oxide.
Figure 3 Schematic representation of our custom-made IR cell used to record spectra from samples in aqueous solutions or as dispersions.

(D₂O) solutions. For temperature control, the gas-tight IR cell is placed into a jacket through which heating or cooling liquid from an external bath circulates. The temperature is monitored at the jacket/cell interface with a thermocouple (t).

Depending upon the diameter and the depth of the recessed surface of the window (i.e. the pathlength of the cell), only a few microliters are required to fill the cell. Moreover, this type of cell can very easily be filled with solution, assembled and disassembled, cleaned between measurements, and provides a constant pathlength, which is very difficult to achieve with conventional tin or polyethylene spacers. The pathlength of the cell can be estimated very precisely by measuring the phase difference in interference fringes caused by internal light reflection of the window surfaces in the empty cell. The relationship between the pathlength of the cell (in centimeters) and the peak-to-peak fringes (ripples) in the spectrum is given by Equation (1):

\[
\text{pathlength} = \frac{n}{2} (v_1 - v_2)
\]

where \(n\) represents the number of complete peak-to-peak fringes between two maxima (or minima) at the wavenumbers \(v_1\) and \(v_2\) (in cm\(^{-1}\)). From a practical point of view, it is interesting to note that all IR transmission cells, if made from suitable high-quality window material, can also be used for measurements in the visible to far-UV spectral region. This allows a variety of measurements such as IR, circular dichroism (CD), and absorption spectra, of the same sample prepared in the same sampling cell.

3.2 The Role of Water in Buffer Subtraction from Protein Spectra

The dominance of water in the spectra of proteins in water-buffered solutions is demonstrated in Figure 2(a), comparing the IR spectra of RNase T1 with a spectrum of the H₂O-based buffer solution applied in the experiment. Whereas some additional spectral features can be seen in the spectrum of the concentrated protein sample (28 mg mL\(^{-1}\)), the original spectrum of the protein at a lower concentration of 7 mg mL\(^{-1}\) (dotted line) is practically indistinguishable from the spectrum of the buffer (solid line). The actual protein bands can only be seen after subtracting the H₂O buffer spectrum from the protein spectrum when measured under identical conditions (Figure 2b). A fourfold increase in protein concentration consistently results in a difference spectrum of higher spectral quality, in which all of the major absorptions expected in the IR spectra of proteins can be identified, but not all proteins tolerate this relatively high concentration without self-association or aggregation.

The precision of the subtraction of water from a protein spectrum requires a reference water band that does not overlap with those of the sample. Often, the combination band of water at around 2126 cm\(^{-1}\) is used to ensure proper subtraction of water, which then results ideally in a straight baseline between 1900 and 2400 cm\(^{-1}\). If positive or negative features are visible in the 2100 cm\(^{-1}\) region of the water-subtracted spectrum, incomplete or overcompensation of the water features is indicated. If derivative-type artifacts are observed in this region (positive and negative bands), this implies that the spectroscopic characteristics of the water in the sample water are not identical with those of the reference water. The latter artefact may often be observed at very high protein concentrations (>50 mg mL\(^{-1}\)), since the interaction of a protein with water can cause the creation of hydration shells around the protein and therefore modify the water vibrations and hence the shape of the water bands in the IR spectrum. Consequently, the reference spectrum of the H₂O buffer cannot completely match the spectral conditions of the water in the protein solution (containing bulk water plus protein-bound water). While the weak water band at 2126 cm\(^{-1}\) (which is more than six times less intense than the water band of interest at around 1645 cm\(^{-1}\)) may serve as a good approximation to subtract the water features interactively, it is necessary to perform the final water subtraction based on a different spectral region with stronger water absorptions. The side lobes of the strong water band of the stretching vibrations (range 3000–3700 cm\(^{-1}\)) are ideal for this subtraction.
Peptides or proteins have only very weak IR bands in the 3000–3100 cm\(^{-1}\) region (see Figure 2b). Residual absorbance in the difference spectrum at 3080–3100 or \(\sim 3650\) cm\(^{-1}\) may serve as a very sensitive monitor for incomplete water compensation.

### 3.3 Effects and Consequences of the Replacement of Water with Deuterium Oxide in Buffers

One way of overcoming the problems related to the strong water absorbance in the amide I region is to replace \(\text{H}_2\text{O}\) in the buffer with \(\text{D}_2\text{O}\). The IR bands of \(\text{D}_2\text{O}\) occur at lower wavenumbers than those of \(\text{H}_2\text{O}\), owing to the downshifted vibrations of the almost twice as heavy deuterium atoms. This isotopic effect creates a region of relatively low absorbance between 1400 and 1800 cm\(^{-1}\), an ideal window for observing the weak IR bands of the dissolved peptide or protein. Much longer pathlengths of 40–80 \(\mu\text{m}\) may then be used, hence much lower sample concentrations are required to obtain high-quality spectra, which is of particular practical interest for proteins of low solubility.

Figure 4 shows IR spectra of RNase T1 in \(\text{D}_2\text{O}\) buffer at protein concentrations of 14 (dashed line) and 1.4 mg mL\(^{-1}\) (dotted line), together with the spectrum of the \(\text{D}_2\text{O}\) buffer (solid line). The buffer-subtracted spectrum (Figure 4b) illustrates that a spectrum with a good signal-to-noise ratio may be obtained from 10 \(\mu\text{L}\) of a 1.4 mg mL\(^{-1}\) protein solution prepared in an IR transmission cell with a 45 \(\mu\text{m}\) pathlength. Measurements of lower protein concentrations are feasible, but below values of approximately 0.5–1 mg mL\(^{-1}\) the noise in the spectra becomes too great to enable some of the approaches described later in this article to be applied.

A specific feature of protein studies in \(\text{D}_2\text{O}\) is the exchange of amide protons into deuterons, which in consequence causes changes in the spectrum after a peptide or protein has been introduced into \(\text{D}_2\text{O}.\) The most dramatic change is a substantial decrease in the intensity of the amide II band (predominantly originating from peptide N–H bending modes, coupled with C–N stretching modes) which is centered near \(1545\) cm\(^{-1}\) in \(\text{H}_2\text{O}.\) This band shifts down in frequency by nearly \(100\) cm\(^{-1}\) to \(1450\) cm\(^{-1}\) (amide II\(_0\)) in \(\text{D}_2\text{O}\), thereby revealing side-chain vibration bands of the protein such as those of arginine, tyrosine, aspartic acid and glutamic acid in the range \(1490–1610\) cm\(^{-1}\). The intensity changes of the amide II band of a protein in \(\text{D}_2\text{O}\) can be efficiently used to monitor hydrogen–deuterium exchange, providing valuable information concerning the structure and flexibility of a protein.

Compared with the large effects on the amide II band, the shift of the nearby amide I band upon deuteration of the backbone hydrogens (labeled amide I by convention) is relatively small (5–10 cm\(^{-1}\)). This can be explained by the fact that this band reflects mainly the carbonyl stretching vibration of the amide group and is therefore less sensitive to the H–D exchange. Nevertheless, individual spectral components of the amide I band reveal different exchange kinetics. Amide protons exposed to the solvent and involved in irregular or turn conformations exchange rapidly, whereas NH groups in stable secondary structures are typically resistant to exchange even after prolonged exposure to \(\text{D}_2\text{O}.\) This greatly assists the assignment of absorption bands arising from different secondary structural classes. Despite the positive aspects, it can also complicate the interpretation of the amide I region if a protein cannot be completely exchanged. In order to ensure that the spectral changes observed arise solely from changes in secondary structure, it is necessary to exchange completely all peptide protons.

![Figure 4](image-url)

**Figure 4** (a) IR spectra of RNase T1 in \(\text{D}_2\text{O}\) buffer at a protein concentration of 14 mg mL\(^{-1}\) (dashed line) and 1.4 mg mL\(^{-1}\) (dotted line), together with the buffer spectrum (solid line). (b) IR spectra of RNase T1 after subtraction of the buffer spectrum.
of the protein backbone before any conformational changes can be investigated in detail. While complete H–D exchange is often attainable in peptides, it typically requires considerable effort in the case of proteins, and often it cannot be achieved at all without irreversible alterations to the structure (e.g. causing aggregation). Figure 5(a) and (b) summarizes the spectral effects of partial and complete deuterium exchange on the amide bands of a protein spectrum. The solid line in Figure 5(a) represents the IR spectrum of the small globular protein RNase T1 that has been allowed to exchange in D₂O buffer for 3 h at room temperature. The residual intensity in the amide II region at about 1550 cm⁻¹, together with the presence of the amide A band (N–H stretching vibrations of the peptide groups) centered at 3295 cm⁻¹, indicate that a significant number of the amide protons are not exchanged after 3 h of exposure to D₂O. This situation is common in many proteins.

The amide A band is the best indicator for residual nonexchanged N–H groups owing to the lack of other protein absorptions in the range 3200–3300 cm⁻¹. The same assessment cannot easily be made based on the residual intensity in the amide II region, since IR bands arising from amino acid side-chain groups overlap with the remaining amide II band, e.g. in RNase T1 the two bands are at 1515 and 1576 cm⁻¹. Complete deuteration of RNase T1 was achieved by keeping the protein solution close to the denaturation temperature for 10 min before cooling back down to room temperature (Figure 5a, broken line). The thermal unfolding of RNase T1 is known to be fully reversible, whereas other proteins may start to aggregate irreversibly upon thermal denaturation. In most cases, keeping the temperature 10°C below the denaturation temperature accelerates the exchange without changing the protein structure. It also seems to be possible to destabilize the protein structure slightly by changing the pH and/or adding chemical denaturants to achieve the accelerated exchange. In any case however, it is necessary to demonstrate that the pretreatment does not irreversibly alter the native protein structure.

3.4 Attenuated Total Reflection as an Alternative to Transmission

Another sampling technique widely used for obtaining IR spectra of biological systems is attenuated total reflection (ATR).⁶ For ATR measurements the sample is prepared on the surface of an IR-transparent medium of high refractive index, usually a zinc selenide, diamond, silicon, or germanium crystal. The IR beam is guided through the crystal in such a way that one, three or several total reflections take place at the surface. Since the IR beam penetrates slightly into the surrounding medium, the deposition of an IR absorber on the crystal surface causes the IR light to be partially absorbed. In this way, a spectrum of the sample may be recorded. The penetration depth of the IR radiation in this arrangement is strictly dependent on the wavelength and the IR spectrum measured therefore contains only information on a very thin layer of the sample that is in close proximity to the surface of the crystal. This allows a spectrum of a protein in H₂O solution to be obtained relatively easily, without much interference from IR absorption of the bulk water.

Specially designed temperature-jacketed ATR cell configurations are available, which also permit experiments under temperature control. Surface adsorption, however, may significantly change the secondary structure of the proteins molecules, which are in direct contact with the crystal. Although the contribution of those molecules to the total absorbance measured may be small, one should
proceed with caution in structural studies of water-soluble proteins by ATR spectroscopy.

Since the amount of sample required to obtain spectra with adequate signal-to-noise ratios by ATR techniques is similar to that required for the transmission experiments described previously, there seems to be no real advantage to using the ATR IR approach for the analysis of water-soluble proteins. ATR techniques, however, are particularly well suited for the study of membrane-associated peptides or proteins. Here, strong adhesion of a membrane film on the ATR crystal may be of advantage. Studies of immobilized samples oriented on the surface of an ATR crystal, such as in membrane-oriented proteins, may be performed with polarized IR light (IR dichroism), providing information on the spatial orientations of functional groups. Compared with classical IR dichroism measurements in transmission mode, the number of layers deposited on the crystal may be much lower, usually resulting in a more uniform orientation. Furthermore, sophisticated ATR techniques allow periodic stimulation of the membrane system by modulation of an external parameter, such as temperature, concentration, or electric field. This results in periodic modulation of only those absorption bands which are related to molecules, or parts of them, that are affected by the external perturbation, and even minor spectral changes within the large background of the total absorbance can be detected.

3.5 Water Vapor and its Effects on Protein Analysis

Another general sampling consideration is that of water vapor and carbon dioxide in the instrument atmosphere. Water vapor and carbon dioxide absorb strongly, and it is necessary to purge the instrument with dry air or nitrogen. This will drastically reduce their level, but it is almost impossible to remove all water vapor and carbon

![Figure 6](image-url)

**Figure 6** Effect of improper water vapor subtraction on the IR spectra of RNase T1 in D$_2$O buffer. (a) Water vapor obtained by subtracting two buffer spectra collected at different instrument purge levels; (b) spectrum of the protein at correct level of water vapor subtraction; (c) spectrum of the protein with water vapor slightly undersubtracted; (d) second derivative of the protein spectrum shown in (b); (e) second derivative of the slightly undercompensated spectrum shown in (c). Some of the peaks that result from undersubtraction of water vapor are marked with asterisks.
dioxide no matter how long the spectrometer is purged. In addition, the level always changes when the sample chamber is opened up and the effectiveness of the purging of the instrument varies during the measurements. It is therefore convenient to record spectra of water vapor at low but well-matched levels for the sample and the reference, rather than waiting for the final purge level of the system between different experiments. A sample shutter that allows the background to be signal averaged almost concurrently with the sample is instrumentally very helpful. Residual water vapor can then simply be subtracted from the sample spectrum by using prerecorded water vapor spectra. This is mandatory for peptide or protein measurements, since the narrow water vapor bands overlap with the conformation-sensitive amide I/II bands (see Figure 6a–e). For aqueous solutions, subtracting two buffer spectra from the same cell collected at different instrument purge levels (Figure 6a) should generate the correct reference water vapor spectrum. Any over- or under-subtraction of water vapor can best be visualized by calculating the second-derivatives of the spectra, which enhances narrow bands in particular (Figure 6d and e). The subtraction factor must be varied until the second-derivative spectrum is featureless in the range 1850–1750 cm\(^{-1}\), which is normally free of any bands due to the lack of functional groups in the sample molecule studied (see Figure 6d).

### 4 DETERMINATION OF PROTEIN SECONDARY STRUCTURE

Specific information on the secondary structure of peptides or proteins is obtained from the analysis of the various conformation-sensitive amide bands. Some of these bands are more useful than others for conformational studies. By far the best characterized in this respect is the amide I/II band, which represents primarily the C=O stretching vibrations of the amide groups (coupled to in-plane bending of the N–H and stretching of the C–N bonds) and gives rise to IR band(s) between approximately 1600 and 1700 cm\(^{-1}\). The amide I/II bands (I stands for the band measured in water and II the band measured in D\(_2\)O) are established indicators of the protein secondary structure because of their sensitivity to hydrogen-bonding pattern, dipole–dipole interaction and the geometry of the peptide backbone. Typically, the amide I/II band of proteins or peptides consists of a series of overlapped component bands which occur as a result of the secondary structures present in such molecules. As a consequence, the individual component bands that represent different structural elements, such as \(\alpha\)-helices, \(\beta\)-sheets, turns, and irregular structures, are often not resolved and difficult to identify in the broad amide I/II band contour of the experimentally measured spectra. Two approaches are currently used for the quantitative estimation of protein secondary structure from FTIR spectra: those which involve curve fitting of the amide I/II band profiles and those which are based on pattern recognition algorithms.

#### 4.1 Approaches Based on Curve Fitting

Curve-fitting analysis of amide I/II band profiles starts with the choice of input parameters, such as the number of component bands and their positions. Here, techniques for band narrowing such as Fourier deconvolution or derivative spectroscopy are very useful and necessary tools.\(^{10}\) Fourier deconvolution decreases the widths of IR bands and is therefore often referred to as a resolution enhancement technique, although it does not increase the instrumental resolution. It significantly improves the degree to which the individual component bands can be resolved, whereby the relative integrated intensities are maintained. Visualization of overlapping bands can also be achieved by calculating the \(n\)th derivative of the spectrum. Often the second derivative is calculated, which gives a negative peak for every band or shoulder in the spectrum. Because sharp bands are enhanced at the expense of broad ones, derivatization does not preserve the integrated areas of individual components.

Band-narrowing techniques greatly amplify features in the spectra originating from random noise and/or uncompensated water vapor. Therefore, Fourier deconvolution and derivation should only be performed on spectra with a very high signal-to-noise ratio (preferably better than 5000:1) and after elimination of water vapor bands. The estimated number of component bands plus their approximated width, height, and shape are then used as input parameters in an iterative least-squares procedure that attempts to reproduce the measured amide I/II band profile by varying these parameters. For practical reasons, self-deconvoluted spectra should be subjected to curve fitting, because least-squares algorithms work significantly more reliably on spectra with an enhanced profile.

Good-quality fitting is accomplished when different starting conditions generate the same fitting and a difference spectrum between the fitted curve and original spectrum appears to be featureless (within 1% of the total intensity at any position in the spectrum). When a reasonable fit is obtained, the fractional areas of the fitted components are taken as directly proportional to the relative quantities of structural elements they represent. The percentages of different secondary structure elements are then estimated by adding the areas of all component bands assigned to each of these structures and
expressing the sum as a fraction of the total amide I/I' band area.

This curve-fitting approach provided estimates of the secondary structure of about 20 selected proteins, which correlated well with the corresponding values based on X-ray data for these proteins.\(^{(11)}\)

### 4.1.1 Critical Aspects in Defining Typical Bands for Secondary Structure

Further studies revealed that this approach (like all curve-fitting applications) shows some significant inherent problems.\(^{(5,12)}\) First, it is always assumed that the number of component bands estimated by self-deconvolution or derivatization reflects the real number of components. In cases where bands significantly overlap, even the applied band-narrowing procedures will certainly fail to separate the components present. This is especially critical in cases in which these components describe different types of secondary structure. It is therefore not surprising that it is sometimes necessary to include extra component band(s) not identified in the spectra after band narrowing, in order to achieve agreement between IR estimates of secondary structure and structure data provided by the X-ray crystallography. In this context, it is important to be aware that the structural information obtained from crystal structures is based on the hydrogen-bonding pattern observed, whereas the IR spectroscopic information is based on the vibrational behavior of the bonds involved. The middle and the end of an α-helix, for example, show slightly different spectral components, while the definition of a helix in a crystal structure does not consider these effects.

NMR spectroscopy on peptides and proteins in solution confirms the findings of inhomogeneous secondary structure elements as described for α-helices. Nevertheless, the number of band components used in the curve-fitting analysis is therefore always somewhat arbitrary. Another critical step is the assignment of the component bands. The assignment is normally guided by theoretical calculations and by empirical spectral–structural correlations experimentally established for model polypeptides and proteins of known three-dimensional structure. The data in Table 2 can be taken as a general guideline for the approximation of protein secondary structure based on their characteristic amide I' frequencies. They illustrate that amide bands arising from α-helical and irregular structures appear in the same spectral range, while parallel and antiparallel β-sheet structures have relatively distinct features. It is obvious that in some cases overlapping bands of α-helical and irregular structures significantly complicate the assignment of these structures to their band components. If a protein, for example, contains both larger quantities of irregular structures such as extended loops and many different longer and shorter α-helices, additional information should be obtained from CD data, since this methodology can distinguish and quantify these two structural elements. The situation is different in the case of β-sheet structures. Theoretical calculations\(^{(3)}\) suggest that it might be possible to distinguish antiparallel β-sheet structures from their parallel counterparts, since the latter lack the high-frequency band component characteristic of antiparallel alignment of β-strands. Few attempts to verify this suggestion experimentally have been made owing to the lack of model structures for parallel β-sheet conformations. Turn structures are associated with various bands between 1660 and 1690 cm\(^{-1}\), β-turns in particular with a band around 1641 cm\(^{-1}\). The complexity in the amide I region of a protein creates difficulties in unique assignment of an IR band component to a specific type of turn structure, although well-defined bands in IR spectra of defined turns in model structures exist.

The band assignment of 310-helices is still uncertain but two bands at around 1640 and 1662 cm\(^{-1}\) are under consideration. Some proteins contain secondary structures that absorb outside the frequency ranges shown in Table 2. In membrane proteins, α-helices appear to absorb in the range 1658–1662 cm\(^{-1}\), and weak component bands below 1640 cm\(^{-1}\) have been observed in α-helical proteins known to contain no β-sheet structure. Such variations may result from an unusual degree of solvent–protein interactions\(^{(15)}\) (e.g. in bifurcated hydrogen bonds), from distortion of structural elements, or from other factors.

### 4.1.2 Comparability of the Bands Representing Different Secondary Structures

Another assumption in the curve-fitting approach is that the molar absorptivities (integrated IR intensities) of the bands associated with different secondary structural elements are identical. This assumption is at its best a rough approximation. Studies on polypeptides and proteins have revealed that the integrated area of the amide I/I' absorption may vary as the structure of the
4.2 Approaches Based on Pattern Recognition

Quite different approaches to estimate the secondary structure of a protein are pattern recognition methods. These methods use IR spectra of proteins with known three-dimensional structures as a calibration matrix. Spectra are either used directly as a spectroscopic pattern to model the spectrum of the protein to be determined, or indirectly after reduction of the protein spectra into a number of eigenspectra which represent the most important spectral information. Mathematical tools such as partial least-squares analysis\(^{(17,18)}\) and factor analysis\(^{(19–21)}\) are normally applied for the evaluation of the protein spectra. In order to validate the method, a leave-one-out rotation procedure is applied. This involves sequential removal of the spectrum of each protein from the calibration set and estimation of the secondary structure using the remaining proteins as reference. Good correlation has been observed between the secondary structure contents estimated and those derived from corresponding X-ray structures, although the number of proteins included in these studies was limited (only 13–23 proteins were selected by different workers). The best results were obtained for proteins recorded in H\(_2\)O solution, whereas the analysis of the spectra of proteins in D\(_2\)O was less successful. This is not surprising, since variations in the extent of H–D exchange for the different proteins used to create the calibration set results in several band shifts in the amide I' region caused by partially exchanged structures. Nevertheless, the advantage of pattern recognition approaches is that these methods eliminate the inherent subjectivity of the curve-fitting techniques discussed above and they do not require the assignment of individual component bands to different types of secondary structure. However, these methods cannot be freely applied without considering certain limitations. For simplicity, most of the approaches involve normalization procedures that assume equal molar absorptivities for various secondary structures, similar to the curve-fitting analysis described previously. More importantly, the methods encounter difficulties in cases where the spectral features of the protein under study do not reflect the characteristics of the spectra within the calibration set. In such situations incorrect estimation of the secondary structure is very likely, even though the mathematical treatment of the spectral data is formally correct.

An increasing number of observations confirm that some proteins have spectral characteristics that cannot be recognized in the spectra of a reference database, when the number of spectra is still relatively small and does not cover the full range of possible types of conformations. Furthermore, the usefulness of these strategies in secondary structure estimation of partially or completely unfolded states of proteins is not always satisfactory. In this context, the IR methods have many features in common with the corresponding strategies used to analyze CD spectra. The potential sources of error in the IR and the CD methods, however, are different. Thus, the combination of the two approaches is highly recommended in order to obtain a complementary overall picture of protein secondary structure. In addition to these pattern recognition techniques, methods with learning capabilities such as neural nets are now emerging and these will widen the range of spectral analyses possible.\(^{(22)}\)

4.3 Advantage of Comparing Spectra of Known Structures with Those Containing Alterations

Notwithstanding the difficulties and some limitations in the quantitative assessment of protein secondary structure—a situation common to all “low-resolution” methods—IR spectroscopy provides a very sensitive and reliable tool for monitoring, in relative terms, even marginal changes in the conformation of the polypeptide backbone. The IR approach can also provide detailed information about local changes in the microenvironment of side-chain groups difficult to assess with other methods. For example, if the three-dimensional structure of a protein is known and one is interested in demonstrating changes in protein structure caused by external factors such as temperature, solvents, ions or, in more complex systems, the whole environment (i.e. a membrane lipid composition), IR spectroscopy can estimate the induced structural changes. Difference spectra generated between spectra of the original state and the altered state of a protein allow a critical assessment of the new structures induced, based on the knowledge of the three-dimensional structure. Since the strength of IR spectroscopy is the ability to identity spectra by
simple comparison, very small spectral changes can easily be observed and analyzed. In the following sections, selected examples of the types of conformational changes that can be probed by FTIR methods are introduced, together with a description of how this information can be extracted from the experimental data. An extensive review of the tremendous number of papers in this field and a description of all IR-based experimental strategies is beyond the scope of this article, however. In particular, we will not present or discuss in detail the wealth of IR studies on photobiological systems (e.g. hemoproteins, bacteriorhodopsin, or photosynthetic reaction centers). These experiments normally require step-scanning techniques and (using specialized tools) may provide unique information on the structural and functional aspects of the system under study on the nanosecond or picosecond timescale. These methods can also be very specific down to the level of single functional groups in a large molecule. The interested reader is referred to recent reviews.\[23–29]\n
5 UNFOLDING AND FOLDING EVENTS UNDER EQUILIBRIUM CONDITIONS

Studies of unfolding/folding of proteins under equilibrium conditions can be monitored by a number of techniques, including FTIR spectroscopy. The structural alterations to be studied in a protein can be induced as for other methods, ranging from simple changes in temperature and pressure to extremes in pH and the addition of denaturants. The purpose of this section is to discuss the general effects that can be observed by IR spectroscopy when simple parameters (e.g. temperature) or the entire environment (e.g. denaturants) are changed. For a typical pressure experiment, the protein is placed in a specially designed diamond anvil cell, and the pressure is calibrated using α-quartz as an internal standard.\[30]\n
5.1 Thermal Unfolding of Proteins – Irreversible Aggregation

Illustrative applications are FTIR studies on the conformation of the enterotoxic protein cholera toxin, and the effect of receptor binding on the structure and thermal stability of the B subunit.\[31]\n
The toxin molecule is composed of two structurally and functionally distinct subunits A and B. While the A subunit is directly responsible for the toxic activity of the protein, the major role of the B subunit is to initiate the toxin–target cell interaction by binding to the monosialoganglioside G\(_{M1}\) receptor on the membrane surface. As shown in Figure 7(a), the amide I’ band contour of the free B subunit remains unchanged upon an increase in temperature from 24°C to 92°C. In the presence of ganglioside G\(_{M1}\) at the glycolipid to the B subunit monomer molar ratio of 2:1 (b), the ratio of cholera toxin B subunit amide I’ band intensity at 1614 cm\(^{-1}\) to that at 1633 cm\(^{-1}\) as a function of temperature (c). Free B subunit in aqueous solution (+) and B subunit in the presence of oligo G\(_{M1}\) (○) or intact ganglioside G\(_{M1}\) (○). (Reprinted with permission from W.K. Surewicz, J.J. Leddy, H.H. Mantsch, Biochemistry, 29, 8106–8111 (1990). Copyright 1990 American Chemical Society.)
up to about 66 °C, indicating that the protein secondary structure did not change in this temperature interval. A further increase in temperature results in major spectral changes, indicating the denaturation of the B subunit. Upon denaturation, the features representing β-sheet structures (around 1633 cm⁻¹) and α-helices (around 1652 cm⁻¹) in the spectrum of the native protein are transformed into new features displaying a strong band centered at 1614 cm⁻¹ and weaker bands around 1683 and 1644 cm⁻¹. For the analysis of these changes, the ratio of the band intensities at 1614 and 1633 cm⁻¹ was found to be a useful parameter to follow thermal denaturation (Figure 7c). Although the IR spectrum of the receptor also shows a broad IR band overlapping with the amide I’ band of the toxin, this particular ganglioside absorption was found to be very weak in comparison with the protein amide I’ band. In this model system it was therefore permitted to analyze the spectra of the complex in the same way as for the free protein, ignoring the minor spectral contributions of the receptor (Figure 7b). The evaluation shows that binding the toxin either to the ganglioside GM₁ receptor or to only the isolated oligosaccharide moiety of the glycolipid can substantially increase the thermal stability of the B subunit.

A noticeable feature present in the IR spectra of the thermally denatured cholera toxin subunits A and B is a strong and sharp band at 1614 cm⁻¹, normally paired with a second weaker band at higher wavenumbers (here at around 1685 cm⁻¹). These two sharp IR bands (the low-wavenumber band in particular) are indicators (marker bands) for protein aggregation. Their origin is a special kind of extended structure, which is often formed upon aggregation of thermally unfolded proteins.

5.2 The Effect of Point Mutations on the Thermal Stability of Proteins

RNase T₁ belongs to the few proteins that show no signs of aggregation under conditions typical for standard FTIR protein measurements, such as protein concentrations of 5–10 mg mL⁻¹ (for measurements in D₂O) and an extended time frame necessary for collection of the spectra. The two major elements of secondary structure of RNase T₁ are a single elongated α-helix and an extended antiparallel β-sheet composed of three long and two short β-strands. The IR spectrum of native RNase T₁ in D₂O buffer after complete H–D exchange and subtraction of the buffer is dominated by a broad amide I’ band, which exhibits a maximum at 1644 cm⁻¹ and two well-defined shoulders around 1626 and 1678 cm⁻¹ (solid line in Figure 8a). Further details are obscured by the overlapping of the amide I’ band components that represent different elements of secondary structure present in the protein.

As for many other proteins, most of these band components can be resolved by a mathematical procedure of band narrowing such as Fourier self-deconvolution or derivatization. The deconvoluted IR spectrum of native RNase T₁ (solid line in Figure 8b) and also the second-derivative spectrum (solid line in Figure 8c) reveal the presence of seven individual bands in the amide I’ region. They can be assigned to characteristic secondary structure elements, e.g. the IR bands at 1624 and 1633 cm⁻¹.
are assigned to different β-sheet structures. Based on comparative analysis of the spectral features of RNase T1 in H2O, in partially deuterated states, and after complete exchange of all amide protons, it was suggested that the band component at 1657 cm\(^{-1}\) can be associated with the α-helix present in RNase T1. The component at 1644 cm\(^{-1}\) could then be assigned to irregular structures with minor contributions from 3\(\alpha\) and/or β-turn structures all present in RNase T1. The band component at 1666 cm\(^{-1}\) was solely attributed to turn structures, whereas both antiparallel β-sheet structures and turns were associated with the band components at 1678 and 1688 cm\(^{-1}\). After complete thermal denaturation of RNase T1 at 70°C, the IR spectrum of the protein (dashed lines in Figure 8a–c) exhibits only a broad, nearly featureless amide I band contour centered at 1647 cm\(^{-1}\), completely different from the spectrum recorded at 20°C. The broad, featureless amide I band contour suggests that the thermally unfolded state of RNase T1 is predominantly irregular, comparable to a randomly oriented polypeptide chain.

It is interesting to note that the thermal unfolding of the protein also resulted in clear spectral changes in the range 1500–1615 cm\(^{-1}\). In fully exchanged proteins, this region is entirely dominated by amino acid side-chain absorptions of tyrosine (two bands at 1515 and 1615 cm\(^{-1}\)), glutamate (around 1576 cm\(^{-1}\)), aspartate (around 1586 cm\(^{-1}\)), and arginine (around 1597/1609 cm\(^{-1}\)).

From IR spectra collected as a function of temperature, intensity/temperature and frequency/temperature profiles for selected IR “marker bands” can be constructed. The measurement of these spectral changes provides a means of determining standard thermodynamic parameters of a protein, such as transition temperatures (\(T_m\)) and enthalpy changes (\(\Delta H\)). Figure 9(a) shows such intensity/temperature plots for the amide I band at 1625 cm\(^{-1}\) in the spectra of wild-type RNase T1 and three of its variants with altered amino acid composition. This band provides a good monitor of the unfolding of the secondary structure of the slightly different RNase T1 samples. The tyrosine band around 1515 cm\(^{-1}\), on the other hand, provides a particularly useful local monitor to probe the thermal denaturation of the proteins, because the shift in frequency indicates changes in the microenvironment around the tyrosines. Figure 9(b) shows frequency–temperature plots for the tyrosine band of the four RNase T1 samples.

The data in Figure 9(a) and (b) indicate that all three mutant proteins display a decrease in the thermal transition temperature (thermal stability). The mutation Tyr-45 → Trp affects \(T_m\) less than the replacement of Trp-59 by Tyr in both the single (W59Y) and the double (Y45W/W59Y) variant.

The temperature dependence of the different IR “marker bands”, which probe different structural features of the protein, permits us also to address the question of whether or not unfolding can be fitted by a two-state unfolding model. If the temperature profiles of two (or more) bands coincide then this is a strong indication in favor of such a model, although it cannot be excluded that corresponding signals may be insensitive to one of the transitions in some cases. If corresponding profiles do not coincide, it clearly indicates that intermediates are present at equilibrium and hence a simple two-state transition cannot be used for analysis of the data. It is a specific advantage of the FTTIR spectroscopic approach that such information can be derived from a single experiment with a single sample.
5.3 Impact of Point Mutations on the Structure of Proteins Examined by Infrared Difference Spectroscopy

The study of marginal changes in protein structure by IR difference spectroscopy can provide information on changes of single peptide bonds or side-chain groups, but has been limited for many years to studies of light-triggered chromophoric proteins, as those spectra can be measured with minimal sample manipulation and without removal from the FTIR instrument. The quantitative comparison of spectra of different samples, often recorded at different protein concentrations, requires an internal standard for their normalization. The well-separated tyrosine band at around 1516 cm$^{-1}$ is a useful internal reference to normalize the spectra of a wild-type protein and its mutants. In the case of proteins which do not aggregate upon heat denaturation, the IR spectra of thermally unfolded proteins provide an ideal internal intensity standard for the quantitative comparison of spectra of related native proteins.\(^{(33)}\) This is illustrated in Figure 10(a) and (b) for the protein RNase T1. Figure 10(a) shows the IR spectra of wild-type RNase T1 (dashed line) and the mutant Y45W/W59Y (solid line) after normalizing both data sets based on the integrated intensity of their spectra in the thermally unfolded state. Figure 10(b) shows IR difference spectra between the wild-type protein and some variants. Positive and negative features in these difference spectra reflect fine structural differences, in whose absence only a flat line is obtained.

An essential prerequisite for this kind of data evaluation is that the spectra have been recorded with a very high signal-to-noise ratio, and that the stability of the instrument is also very high, otherwise minor spectral differences will be “buried” within the noise. Clear spectral differences (at 20°C) can be observed between wild-type RNase T1 on the one hand and the two variants Y45W/W59Y and W59Y on the other, whereas practically identical difference spectra in the amide I region were obtained for the double variant Y45W/W59Y and the single variant W59Y (compare traces A and B in Figure 10b). This demonstrates that it is the change from Trp to Tyr in position 59 which affects the overall protein conformation. In particular, the positive bands at 1628 and 1635 cm$^{-1}$, along with the negative band at 1622 cm$^{-1}$ in these difference spectra, reflect fine differences in the hydrogen-bonding pattern of $\beta$-structures in the two variants, compared to the wild-type protein. The mutation Tyr to Trp in position 45, on the other hand, has practically no impact on the polypeptide backbone conformation, as indicated by the almost flat difference spectrum (trace C in Figure 10b). This was found to be in good agreement with X-ray data, and demonstrates the sensitivity of the IR spectroscopic approach.

5.4 Chemically Denatured States of Proteins

Obtaining IR spectra of proteins in the presence of the most commonly used denaturating agents, urea and guanidinium chloride (GdmCl) is not simple, and has been unsuccessful for a long time for several reasons. First, the denaturant that must be used at high concentrations to achieve a significant structural alteration has very strong IR bands of its own. Therefore, IR cells with very short pathlengths (5–7 μm) are required to prevent saturation of the IR detector by absorption of the chemical denaturant. Second, the major IR band of urea around 1613 cm$^{-1}$ (Figure 11a, dashed line) or GdmCl around 1600 cm$^{-1}$ (Figure 11b) masks the much weaker protein backbone modes of interest and prevents their analysis. Isotopic labeling of the denaturant (e.g. using $^{13}$C=O-labeled urea) is a suitable method for helping to circumvent this problem by shifting the urea band from 1613 to 1560 cm$^{-1}$ (compare the dashed and solid lines in Figure 11a). In this way, isotope labeling creates a clear window in the IR spectrum for observing the protein amide I bands above 1600 cm$^{-1}$\(^{(34)}\). This strategy allows the measurement of chemically induced unfolding transition of proteins as described by other methods and enables us to compare conformational features of thermally and chemically denatured states.
of the same proteins\textsuperscript{(34–36)} or of slightly different proteins.

6 ANALYSIS OF PEPTIDES

FTIR spectroscopy is also extensively used in conformational studies of shorter and longer peptides.\textsuperscript{(37)} Typical applications include the analysis of the formation of secondary structures and their changes when peptides were subjected to environmental perturbations (e.g. temperature, pressure, pH, addition of organic or membrane-mimicking solvents). In some cases, the impact of point mutations or amino acid modifications (e.g. D-amino acid substitution, amidation, phosphorylation) on the structure and stability of peptides was studied. More difficult, but very beneficial to the understanding of membrane effects on proteins structures, are studies aiming to monitor changes in the conformation of a peptide resulting from an interaction with a membrane.

Nevertheless, some difficulties exist in the quantitative assessment of the secondary structure of peptides from IR spectra. Primarily, this is because the position of an IR band associated with a certain secondary structure in a peptide can be significantly different from that of the corresponding structure in a globular protein. For instance, $\alpha$-helical structures in globular proteins typically show absorption in the range 1650–1658 cm$^{-1}$, while the position of a band of an $\alpha$-helical structure in a solvent-exposed peptide may occur below 1640 cm$^{-1}$.

Since the pattern recognition methods discussed previously rely on calibration spectra obtained almost exclusively from globular proteins, these approaches may not (yet) be applied for secondary structure estimation of peptides. Hence the curve-fitting approach is often applied for this purpose, despite the weaknesses associated with band assignment. In proteins, differences between the H–D exchange kinetics of amide protons in irregular structures (very fast) and in $\alpha$-helical structures (often very slow) can aid band assignment. In peptides, however, this strategy usually does not help very much, since isotopic exchange in $\alpha$-helical segments of peptides is typically also fast. Here, FTIR and CD spectroscopy should both be applied, since the latter method is known to be more suitable for quantifying $\alpha$-helical structures. Moreover, IR spectra of peptides often reveal relatively structureless amide I band contours, even after the application of resolution-enhancement techniques. This implies a large degree of subjectivity in the estimation of the number of band components and their relative contribution to the total amide I band contour. An exception is the analysis of antiparallel $\beta$-type structures, which can readily be identified by characteristic amide I band components near 1620–1635 cm$^{-1}$ (very strong) and near 1675–1690 cm$^{-1}$ (weak).

The potential of FTIR spectroscopy to indicate very sensitively the presence of, and changes in, $\beta$-pleated sheet structures has been employed to characterize conformational properties of synthetic analogs of peptides known to be associated with pathological conditions such as Alzheimer’s disease and the spongiform encephalopathies. These neurological disorders have in common an aberrant conformational transition in an underlying peptide/protein, characteristically leading to aggregated $\beta$-sheet assemblies and tissue deposition. The IR approach does not provide structural details of the arrangement of such assemblies of a synthetic analog, but is useful in studying the impact of environmental factors, naturally occurring point mutations or chemical modifications on conformation and stability.

6.1 Alzheimer $\beta$-Amyloid Peptides

As an example for peptide analysis, Figure 12(a–c) shows IR spectra of analogs of a 42-amino acid peptide, called $\beta$A4, known to be involved in the formation of neuritic plaques in patients with Alzheimer’s disease.
The comparative study of two peptides, a synthetic peptide corresponding to the normal human sequence \([\text{H}(1–42)]\) (dashed line) and the variant containing isoaspartic residues in positions 1 and 7 \([\text{I}(1–42)]\) (solid line) recorded in different environments. In \(\text{D}_2\text{O}\) at pH 8 (a), in \(\text{D}_2\text{O}\) at pH 11 (b), and in 10% octyl-\(\beta\)-D-glucoside at pH 8 (c). All spectra are shown after band narrowing by Fourier self-deconvolution performed with identical deconvolution parameters.

6.2 Membrane-associated Peptides/Proteins

FTIR spectroscopy has proven to be of particular value in probing conformational transitions in peptides/proteins caused by the interaction and association with lipid bilayers or natural membranes. Such changes are thought to be important for understanding a number of physiological processes. Studies of membrane-associated peptides or proteins are often difficult to perform by other spectroscopic techniques, e.g. owing to spectral distortions caused by light scattering. An advantage of FTIR spectroscopy is that it provides structural and dynamic information on both the peptide/protein and the lipid components simultaneously, and that extra probes and marker molecules are not required. In addition, polarized IR spectroscopy can be used to measure the average orientation of peptides/proteins with respect to the plane of the membrane. Moreover, isotope labeling, combined with site-directed mutagenesis, now makes it possible to scrutinize conformational properties at the level of individual chemical groups. The latter strategy has been elegantly demonstrated on phospholamban (PLB), a small membrane protein which can form cation-selective ion channels in lipid bilayers. The protein is anchored in the membrane by a 28-amino acid fragment corresponding to its C-terminal region (hPLB). Polarized ATR FTIR spectroscopy along with site-directed isotope labeling was used to probe the local structure of hPLB.\(^{41}\)

Figure 13 shows the spectra of dehydrated films of hPLB and hPLB labeled at both Leu-39 and Leu-42 amide carbonyl groups. The amide I and amide II bands of hPLB are located at 1658 and 1544 cm\(^{-1}\), indicating a predominantly \(\alpha\)-helical structure for the peptide reconstituted into dimyristoylphosphatidylethanolamine (DMPC) at 1643 cm\(^{-1}\), characteristic of a peptide with only little regular secondary structure. In contrast, the spectrum of the I-peptide still exhibits strong bands at 1627 and 1684 cm\(^{-1}\), indicating a significant amount of \(\beta\)-type structure in the modified peptide at pH 11. For peptide analysis, organic solvents or others are often employed to probe the propensity of a peptide to form an \(\alpha\)-helix (in trifluoroethanol) or to mimic a micellar environment (e.g. sodium dodecyl sulfate, octyl-\(\beta\)-D-glucoside, or aqueous acetonitrile solutions). In principle, IR spectra of peptides in these solvents can be recorded as readily as in pure aqueous solution. However, care must be taken to subtract properly the solvent/buffer spectrum (the solvents have IR bands of their own overlapping with bands of the peptide) and to avoid evaporation of the very volatile solvents after filling the IR cell. The spectra of the \(\beta\)-amyloid peptides in octyl-\(\beta\)-D-glucoside (Figure 12c) can be taken as textbook examples of antiparallel \(\beta\)-sheet structures.
Figure 13 Comparison of ATR FTIR spectra of the unlabeled C-terminal sequence of hPLB and [1-13C]-L39,L42-hPLB recorded using parallel polarization. Measurements were performed on dehydrated films. Inset: comparison of the expanded region near 1614 cm⁻¹ of unlabeled hPLB, [1-13C]-L39-hPLB, and [1-13C]-L39,L42-hPLB. (Reproduced by permission of the Biophysical Society from Lundlam et al.41)

bilayer membranes. The other two intense bands in the spectrum, which are well separated from the peptide backbone modes, are associated with the DMPC ester carbonyl stretching mode (at 1738 cm⁻¹) and the CH₂ scissoring mode (at 1486 cm⁻¹). The replacement of a ¹²C=O group with a ¹³C=O group decreases the amide I vibration by 40–45 cm⁻¹ owing to the increased mass. Labeled amino acids are commercially available and can be incorporated during peptide synthesis without additional effort. Utilizing this approach, comparison of the spectra of unlabeled and labeled peptides allows the identification and analysis of the amide I bands that originate exclusively from the labeled site. This is clearly shown in the spectra of hPLB (Figure 13). A drop in intensity at 1658 cm⁻¹, together with the appearance of a new band at 1614 cm⁻¹, is observed, which can be assigned to the isotope-induced downshifted amide I modes of Leu-39 and Leu-42. This assignment is supported by the fact that the intensity of the band near 1614 cm⁻¹ has only approximately half the intensity in the spectrum of hPLB labeled at only Leu-39 (Figure 13, inset). The position of the amide I modes of Leu-39 and Leu-42 indicates that both residues are part of an α-helical structure and therefore residue i + 4 (e.g. 46 = 42 + 4) must also be in a helical geometry. The same holds for the nearby residues, which contribute to the hydrogen bonding scheme of the α-helix. That means that a single label can report on the local secondary structure of four residues. Hence it was concluded that six isotopic labels would be the minimum needed to define a transmembrane helix (~22 amino acid residues).141 Moreover, the IR linear dichroism (data not shown) of the amide I bands assigned to the labeled sites suggested an α-helix with an axial orientation of 30° relative to the membrane normal. H–D exchange measurements revealed that 70% of the amide protons, including the peptide groups of Leu-39 and Leu-42, are inaccessible to the solvent, indicating that most of the hPLB fragment is embedded within the lipid bilayer.

Site-directed isotope labeling is so valuable to FTIR spectroscopy that its application allowed the study of local changes in the polypeptide backbone occurring during the photocycle in an integral membrane protein, bacteriorhodopsin.6,42 In this case, L-tyrosine containing a ¹³C isotope at the carbonyl carbon was selectively introduced in a biosynthetic process at specific positions along the polypeptide chain of bacteriorhodopsin. Then structural changes during the transition from the M to the N state were monitored by IR difference spectroscopy. Similar results to those of the hPLB peptide discussed
previously were observed, i.e. a minor drop in intensity of the amide I band assigned to the $\alpha$-helical structure in bacteriorhodopsin, along with the appearance of a weak downshifted amide I band. The characteristic spectral changes were only recorded after labeling at Tyr-185. This demonstrated that of the 11 tyrosines, only the peptide carbonyl group of Tyr-185 undergoes a significant conformational change during the early photocycle. This is an excellent example which demonstrates the sensitivity of FTIR spectroscopy in monitoring one selective bond in a rather large membrane protein.

7 ANALYSIS OF PEPTIDE–PROTEIN AND PROTEIN–PROTEIN COMPLEXES

Extensive overlap of the diagnostic IR bands limits the application of FTIR spectroscopy when a peptide and a protein or two different proteins form a complex. These problems can be overcome by mixing a completely $^{13}$C-labeled protein with an unlabeled peptide or protein. This is illustrated in Figure 14(a–c), which compares the IR spectra of (a) unlabeled calmodulin, (b) $^{15}$N uniformly labeled calmodulin, and (c) $^{13}$C/$^{15}$N uniformly labeled calmodulin. As expected, $^{15}$N labeling produces almost no changes in the amide I $^0$ band contour, owing to the relatively minor C−N stretching contribution to the amide I vibration. On the other hand, $^{15}$N labeling causes a significant shift of the amide II $^0$ band of the protein (from 1457 to 1430 cm$^{-1}$). Complete (biosynthetic) labeling solely with $^{13}$C results in a large low-frequency shift of the amide I $^0$ band of the protein away from the original spectral region, and allows the conformational changes associated with binding of unlabeled synthetic target peptides to calmodulin$^{(43)}$ to be studied individually.

Figure 15(a) shows the IR spectra of $^{13}$C/$^{15}$N uniformly labeled calmodulin (dashed line) and its complex with the calmodulin-binding domain of the peptide MLCK (solid line). It is important to ensure that the generally larger protein, in this case calmodulin (148 amino acids), be labeled by over 99% to prevent the appearance of any residual intensity from the unlabeled protein. This allows the detection of the generally weaker amide I $^0$ bands of the smaller target peptides, in this case MLCK (22 amino acids). A comparison of the spectrum of the MLCK peptide alone and in complex with calmodulin reveals clear differences (compare the solid and dashed lines in Figure 15b). In this case, the carryover counterion TFA used in peptide synthesis, which has a strong IR band at 1674 cm$^{-1}$, was used as an internal reference to normalize the spectra. This permits comparison not only of frequencies but also of intensities between the spectra of the peptide alone and in the peptide–protein complex. The broad and featureless amide I $^0$ band contour of the MLCK peptide centered at 1642 cm$^{-1}$ is typical of an unstructured peptide. The amide I $^0$ band of the peptide in the complex is considerably more intense, narrower, and centered at 1647 cm$^{-1}$, indicating that the peptide has changed from an irregular structure to an $\alpha$-helical conformation upon binding to calmodulin. Spectral differences between 1550 and 1610 cm$^{-1}$ suggest that the binding of the peptide also leads to a slight but perceptible perturbation of the conformation of calmodulin. Recently, the isotope-edited strategy was employed to determine the protein secondary structures of both ligand and receptor in a signal transduction complex.$^{(44)}$
Figure 15 (a) Deconvoluted IR spectra of $^{13}$C/$^{15}$N-labeled calmodulin (dashed line) and its complex with the myosin light chain kinase (MLCK) peptide at a 1:1 ratio (solid line). (b) Comparison of the deconvoluted IR spectrum of the MLCK peptide in D$_2$O buffer (dashed line) and the spectrum of the peptide in complex with $^{13}$C/$^{15}$N-labeled calmodulin (solid line). The IR band resulting from residual internal trifluoroacetic acid (TFA) was used to normalize the intensity of the corresponding peptide spectra.

9 NEAR-INFRARED SPECTROSCOPY AS A TOOL FOR MONITORING STRUCTURAL CHANGES OF PROTEINS IN AQUEOUS SOLUTION

Thus far, IR spectroscopy in the spectral range above 4000 cm$^{-1}$, the near-infrared (NIR) region, has seldom been employed for structural studies of peptides or proteins. The absorptions observed in the NIR region are overtones (multiples) or combinations of the fundamental stretching bands that occur in the mid-IR region. The bands involved are usually due to C—N, N—H, and O—H stretching vibrations. Generally, all these bands are much weaker than in the mid-IR region. In consequence, most of the NIR studies were limited to solid samples. For measurements in aqueous solutions, relatively high sample concentrations (>30 mg mL$^{-1}$) and cells with pathlengths of 0.2–1 mm are required. The latter is feasible, since the water absorption in the NIR region is relatively weak. An illustrative example of the potential of NIR spectroscopy for the characterization of structural changes in proteins is a study of the thermal unfolding of the model protein RNase A in H$_2$O buffer. (46) Spectra
in the mid-IR and NIR regions were measured under identical experimental conditions using the same protein solution with the exception of the cell path length which was required to be about 30 times longer for the NIR studies. The heat-denaturation of RNase A is accompanied by large spectral changes, as illustrated in Figure 16(a) and (b) for the mid-IR region and Figure 16(c) and (d) for the NIR region.

As discussed previously, characteristic changes in the amide I region (e.g. intensity changes of the $\beta$-structure “marker band” at 1641 cm$^{-1}$) can be used to monitor thermal unfolding of the protein. In the NIR region, the most pronounced spectral changes were observed in the range between 4820 and 4940 cm$^{-1}$, where NH combination modes of amide A and amide II can be expected. In the spectrum of RNase A at 20°C the N–H combination band is located at 4867 cm$^{-1}$. With increasing temperature this band loses intensity, becomes broader, and shifts to higher wavenumbers. The frequency–temperature plot for this band reveals that the temperature dependence is similar to the intensity–temperature plot of the backbone C=O amide I band component in the mid-IR region (compare Figure 16a and c). This demonstrates that the N–H combination band can be used as a monitor for the thermally induced unfolding of proteins in H$_2$O solutions. The fact that in the mid-IR N–H stretching vibrations are overlaid with strong water bands and N–H bending vibrations are always overlapped with C–N stretching vibrations makes it difficult to evaluate amide N–H vibrations of proteins in H$_2$O. The N–H combination band offers a new way of achieving this.

10 TIME-RESOLVED FOURIER TRANSFORM INFRARED SPECTROSCOPY, FOLDING EVENTS ON THE MILLISECOND TO MINUTE TIMESCALE

For many years, the use of time-resolved FTIR spectroscopy was restricted to events in photobiological systems where reactions could be triggered with light and were often reversible. Only very recently has progress been made in the adaptation of conventional stopped-flow or temperature-jump technologies to the specific requirements of IR spectroscopy. A major hurdle was the construction of an apparatus which ensured a rapid flow of a concentrated viscous protein solution through an IR cell with a pathlength of only 50 µm. To achieve this, high pressure is needed and the apparatus must withstand this pressure. Furthermore, the dead volume must be kept as small as possible to minimize the amount of protein necessary for these experiments.
A prototype of a stopped-flow apparatus for IR spectroscopy of aqueous protein solutions has recently been developed. Figure 17 shows a schematic diagram of an adapted experimental set-up, which permits the initiation of the refolding process either by applying a temperature jump on the heat-denatured protein or by rapid dilution of a concentrated $^{13}$C urea solution containing the chemically unfolded protein. A pneumatic drive is used to induce either the mixing process of the chemically denatured protein with buffer or the temperature jump of the thermally unfolded protein. The drive is triggered by an electric signal from the spectrometer. The dead time of the injecting or mixing devices and the time resolution of the FTIR spectrometer allow refolding kinetics on the millisecond to minute timescale to be monitored.

Figure 18 shows a series of difference spectra obtained from a typical temperature-jump experiment with the protein RNase A. Decreasing negative features in the difference spectra indicate the formation of secondary structure after a temperature-jump from 80 to 20°C, whereas reduced positive features correspond to a decrease in structure characteristic of the unfolded protein. The negative band at 1631 cm$^{-1}$, which dominates the IR difference spectrum, directly indicates the formation of antiparallel β-sheet structures in the protein. The inset in Figure 18 represents the intensity–time plot obtained employing the prominent difference band at 1631 cm$^{-1}$. As is already known from studies under equilibrium conditions, IR spectroscopy also permits the monitoring of the impact of unfolding/folding on the microenvironment of certain side-chain groups, which primarily indicates changes in tertiary structure arrangements. Tyrosine-detected folding of RNase A employing the band at around 1515 cm$^{-1}$ exhibited slower kinetics than folding monitored by the β-sheet band at 1631 cm$^{-1}$. This clearly indicates that the formation of secondary structure precedes the formation of stable tertiary contacts in RNase A. Moreover, a comparison of the intensity changes observed during kinetic experiments with those observed in equilibrium studies revealed that a significant part of the secondary structure in RNase A is already formed within the dead time (~50 ms) of the present experimental set-up.

The FTIR approach discussed above certainly has great potential to complement established techniques in describing structural events that occur during unfolding/folding of proteins on the millisecond to minute timescale. It is one of the strongest advantages of FTIR spectroscopy that a complete spectrum is available for each time point of measurement. In this way, several spectral windows are accessible simultaneously for the observation of the formation of different secondary structure elements and also folding events that can be attributed to the formation of tertiary contacts. Thus, perfect time correlation is ensured between folding events that can otherwise only be probed by different techniques, which often require different experimental conditions.
On the other hand, the kinetic IR data for RNase A and experimental data for many other proteins also clearly show that there are much faster events in protein folding that must be explored. This, however, requires new and different approaches. One very promising new strategy, which offers both the temporal resolution and the structural specificity, is to combine laser temperature-jump techniques to initiate impulsively the process with single-wavelength IR spectroscopy (using an IR diode laser) to probe the structural evolution of the event. \(^{(49)}\)

Gel electrophoresis is a widely used method in biochemical research; a number of different forms of gel electrophoresis have been developed and applied to the analysis of proteins and peptides. The most popular form is polyacrylamide gel electrophoresis (PAGE), in which proteins are separated within a gel matrix on the basis of differences in their charge density and/or relative molecular mass ($M_r$). Polyacrylamide gel is also widely used as a media for the generation of pH gradients in an isoelectrofocusing (IEF) technique, where separation of proteins is due to their differences in isoelectric point (pI). Two-dimensional (2D) electrophoresis is an extremely powerful separation technique, allowing differentiation of proteins on the basis of their pI in IEF, and their $M_r$ in sodium dodecyl sulfate (SDS)/PAGE. Agarose gels are rarely used today in the electrophoretic analysis of proteins; their utility is mainly restricted to the immunoelectrophoretic techniques, which allow the characterization of proteins by their migration in gel and immunological properties.

This article provides a brief history of gel electrophoresis and describes the principles of major electrophoretic techniques. The utility of gel electrophoresis in different fields of biochemical research is also demonstrated. Topics included are analytical and small-scale preparative separations of complex proteins samples; determination of molecular mass of the electrophoretically separated proteins and polypeptides; electrophoretic micropreparation of a protein sample for its further immunochemical, enzymatic, and chemical analysis; study of protein interactions with different ligands; examination of protein unfolding and its quaternary structure. The advantages and limitations of the described techniques are discussed.

1 INTRODUCTION

Fifty years after the introduction of gel electrophoresis for protein separation, this technique continues to play one of the major roles in protein and peptide research. Different electrophoretic methods, developed using agarose or polyacrylamide as supporting media, have allowed separation of proteins on the basis of their differences in size, charge, and pI. During the 1990s, the importance of electrophoretic techniques, especially polyacrylamide electrophoresis, have increased significantly due to advances in the immunochemical and chemical methods of protein and peptide analysis. The combined use of high-resolution electrophoresis with sensitive immunodetection methods, microsequencing techniques, and mass spectrometry (MS), has become a powerful analytical approach in many biochemical studies. This article presents a brief history of gel electrophoresis, and describes the principles and applications of the major electrophoretic techniques presently used in the analysis of proteins and peptides.

2 HISTORY

Historically, the first form of electrophoresis was moving-boundary electrophoresis in free solution, in
which an electric field applied to a solution of protein mixture resulted in migration of proteins to electrodes at a rate depending on the charge density of the molecules. This technique was modified to zone electrophoresis in free solution, where the proteins to be separated were placed as a narrow zone at a suitable distance from electrodes. This method was subsequently replaced by zone electrophoresis in solutions stabilized within supporting media, such as paper, cellulose acetate, thin-layer material (silica gel, alumina, cellulose), and gels of agar, agarose, and polyacrylamide. These supporting media minimized the deleterious effects of convection and diffusion associated with electrophoresis in free solution. They also allowed fixation of separated proteins at their final position immediately after electrophoresis. The use of gels as supporting media was of particular importance – in contrast to paper, cellulose acetate, or thin-layer materials, gels can be considered as porous media in which the separation of proteins is dependent on both charge density and size.

In the early 1950s, zone electrophoresis in agar gels was a popular technique for separation of serum proteins, especially when combined with the immunotechnique of Grabar and Williams. However, owing to the presence of sulfate and carboxyl groups, agar gels suffered from marked electro-endosmosis and from protein losses due to absorption. Therefore, after the introduction of agarose – a neutral component of agar – in electrophoretic studies. The method of starch gel electrophoresis pioneered by Smithes in 1965 dramatically improved the resolution of serum proteins and was widely adopted for analytical purposes. Starch gels have pores of the same order as protein molecules, thus contributing an efficient molecular sieving effect. In this respect starch is advantageous over agarose, where pore size is sufficiently larger and thus the molecular sieving of most proteins is minimal. However, as starch is a natural product, its composition can vary affecting the gelling ability, resolution and reproducibility of the results. Therefore, after the introduction of polyacrylamide gel – a synthetic polymer of acrylamide monomer – for protein electrophoresis, starch gel electrophoresis became almost entirely superseded by this technique. Similarly, electrophoretic separation of proteins in agarose gels was eclipsed by the use of polyacrylamide. However, agarose gel remains widely used in immunoelectrophoretic procedures and in the separation of very large molecules, such as nucleic acids and lipoproteins.

During the period from about 1960 to 1970 many different forms of PAGE were developed, including continuous and discontinuous, dissociating and nondissociating buffer systems. The technique of SDS/PAGE, first described by Shapiro et al. in 1967 and further modified by Laemmli in 1970, has become one of the most widely used electrophoretic methods. Other remarkable events of this decade were the publication of the theory of IEF by Svensson in 1961 and invention of the procedure for the synthesis of carrier ampholytes (CAs) by Vesterberg and Svensson in 1964. The synthetic amphotropic buffers, were used to generate and stabilize the pH gradient in IEF, thus allowing the proteins to be focused at their isoelectric points. The utilization of polyacrylamide gel matrix made the IEF technique extremely popular. Remarkable progress in immunoelectrophoretic techniques has been made with the introduction of rocket and crossed immuno-electrophoresis.

The 1970s marked further rapid development of polyacrylamide slab gel electrophoretic techniques. High-resolution 2D electrophoresis combining IEF and SDS/PAGE, was reported in 1975. A method of peptide mapping was developed which involved partial proteolysis of the electrophoretically separated proteins and further analysis of the resulting peptides by SDS/PAGE. Silver staining, introduced in 1979 as a novel procedure for protein staining in gels, was 100-fold more sensitive than the commonly used Coomassie Blue R-25. The method of electrophoretic transfer of proteins from polyacrylamide gels to nitrocellulose sheets was described in 1979; it gained widespread application in the immunochemoical identification of proteins.

In the early 1980s, the first report on IEF in immobilized pH gradients (IPGs) appeared. In the IPG technique, the buffers forming the pH gradient are covalently attached to the polyacrylamide matrix, thus enabling the generation of more reproducible and stable pH gradients in comparison to conventional IEF.

Since the mid-1980s, with the advent of gas-phase automated protein sequencing and the introduction of inert transfer membranes compatible with microsequencing procedure, gel electrophoresis has emerged as an extremely useful sample preparation technique for amino acid sequence analysis. Separation of complex protein mixtures by one-dimensional (1D) or 2D electrophoresis followed by electroblotting of proteins on to poly(vinyl difluoride) (PVDF) membranes became a common approach for direct N-terminal sequencing. The techniques have been described for the generation of peptide fragments in order to obtain information on internal sequences of gel-separateted proteins.

In the early 1990s, MS demonstrated its ability to analyze gel separated proteins, especially using 2D separations. Both matrix-assisted laser desorption/ ionization (MALDI)/MS and electrospray ionization (ESI)/MS provided routes to determine accurate masses
of intact proteins and peptide fragments. Computer programs have been developed to identify proteins by using the experimentally obtained peptide masses for peptide-mass database search.

At present, polyacrylamide slab gel electrophoresis, in conjunction with highly sensitive detection techniques, represents one of the most powerful analytical tools in protein and peptide research. Polyacrylamide gel matrix is also used in the rapidly developing technique of capillary electrophoresis (this issue is discussed in article Capillary Electrophoresis in Peptide and Protein Analysis. Detection Modes for). In light of the interface of electrophoretic techniques with amino acid sequence and mass spectral analyses, gel electrophoresis has gained wide application as an analytical method and as an important microtechnique for the isolation and purification of proteins and peptides.

**3 METHODS OF GEL ELECTROPHORESIS: PRINCIPLES, BASIC TECHNIQUES, AND EQUIPMENT**

**3.1 One-dimensional Polyacrylamide Gel Electrophoresis**

**3.1.1 Polyacrylamide Gels**

The most widespread technique for electrophoretic analysis of proteins and peptides is zone electrophoresis in polyacrylamide gels, where the macromolecules are separated on the basis of their charge and/or size. Polyacrylamide gel is obtained by the polymerization of acrylamide monomers into long chains and their cross-linking using \( N,N' \)-methylene bisacrylamide. Polymerization is initiated by the addition of riboflavin or ammonium persulfate. \( N,N,N',N'\)-tetramethylenediamine (TEMED) is added to accelerate this process by catalyzing the formation of free radicals from persulfate, which in turn initiate the polymerization. The effective pore size of the gels decreases as the acrylamide concentration increases. For any given total concentration of monomers (%T, i.e. gram acrylamide plus bisacrylamide per 100 mL), the effective pore size and physical properties of polyacrylamide gel vary depending on the proportion of the cross-linker (%C; concentration of crosslinker relative to %T, weight for weight).

**3.1.2 Buffer Systems**

Electrophoresis of proteins can be carried out under nondenaturing conditions in order to study native proteins, or under denaturing conditions by employing the dissociating agents, i.e. detergents (usually the anionic detergent SDS), urea, and disulfide cleavage agents (β-mercaptoethanol or dithiothreitol (DTT)). The SDS binds to different polypeptides in an approximately constant ratio of 1.4 g SDS per gram of polypeptide. The resulting SDS–polypeptide complexes have essentially identical densities of negative charge provided by the detergent, and thus migrate in PAGE according to their molecular mass (section 4.1). Urea acts by disrupting the hydrogen bonds. In contrast to SDS, urea does not affect the intrinsic charge of proteins, so the electrophoretic separation of the constituent polypeptides in presence of urea occurs on the basis of both charge and size. The systems employing both urea and SDS have been described and found to be effective in obtaining high resolution of proteins and small peptides (section 4.1).

The electrophoretic techniques also vary in respect of whether the buffers used are homogeneous (continuous) or multiphasic (discontinuous). In homogeneous buffer systems the same buffer ions are present at constant pH throughout the sample, gel and electrode vessel reservoirs. In multiphasic systems the composition and pH of the buffers are different in the electrode reservoir and in different parts of the gel. In most multiphasic systems a sample is loaded on to a large-pore stacking (upper) gel, in which the proteins are effectively concentrated prior to their separation in the small-pore resolving (lower) gel. In the Ornstein–Davies discontinuous system the sample and the stacking gel contain Tris (tris(hydroxymethyl)aminomethane)–HCl (pH 6.7) buffer, whereas the reservoir buffer consists of Tris–glycine (pH 8.3). In continuous SDS/PAGE as described by Weber and Osborn and by Swank and Munkres, sodium phosphate buffer was applied. The popular Laemmli method is based on the discontinuous Ornstein–Davies system with SDS present. The alternative SDS dissociating system described by Neville employed Tris–borate buffer. The discontinuous Tris–Tricine (N-tris(hydroxymethyl)methyl)-glycine) and Tris–Bicine (N,N-bis(2-hydroxyethyl)-glycine) SDS/PAGE methods have been developed, allowing effective separation of many proteins over a broad range of their molecular mass. The commonly used SDS discontinuous buffer systems are presented in Table 1.

The SDS/PAGE techniques described above are not always suitable in cases where the native protein conformation and biological activity must be preserved. Unfortunately, there is no universal buffer system ideal for the separation of native proteins. Contrary to SDS/PAGE, where the protein–SDS complexes are negatively charged over a wide range of pH, separation of proteins in nondissociating systems is highly dependent on pH. Here, changes in pH can alter the net charge of protein and affect negatively its separation, as well as its biological activity. Therefore, a large number of
systems have been designed for use at any pH; systems resolving proteins at pH 3.8 (37), pH 8.0 (35), and pH 9.5 (36) are commonly used. (37)

3.1.3 Gel Concentration

The commonly used concentrations of polyacrylamide gels vary from 5 to 20% depending on size or charge of protein under study. For the analysis of proteins with an unknown molecular mass the optimal gel concentration can be determined experimentally by starting with 7.5% acrylamide gel and then checking the range from 5 to 15%. Protein mixtures can also be separated by using a concentration gradient in which the concentration of acrylamide increases in the direction of protein migration. Gradient gels are commonly used in SDS/PAGE and are especially useful when complex protein mixtures that cover a wide range of molecular mass must be displayed in a single gel.

3.1.4 Equipment

The equipment for both rod and slab gel electrophoresis is commercially available from many suppliers. However, in many cases the flat slab gel configuration is preferred. First, by using slab gels many samples can be run simultaneously under identical conditions in a single gel. Second, proteins run on the slab gel can be easily transferred to thin blotting membranes for their further analysis. The vertical slab gel apparatus available from Bio-Rad Laboratories and Hoeffer-Scientific Instruments are designed to run small-format slab gels (10 × 8 cm or 12 × 10 cm) and represent the most widely used models. NuPAGE electrophoretic systems including running cell, precast gels (of single and gradient concentration), ready-to-use buffers of neutral pH, and staining kits are now available from Novex (USA). This system provides rapid, reproducible and high-resolution separations under both dissociating and nondissociating conditions.

3.1.5 Detection

Various methods have been reported for the detection of proteins separated on polyacrylamide gels. In early studies the commonly used organic dye was Amido Black 108. Later it was replaced by the more sensitive Coomassie Blue R-250 (or G-250) allowing detection of 0.2–0.5 µg of any protein in a sharp band. With the introduction of silver staining (21) the detection sensitivity was increased up to 100 times. However, silver staining is a more laborious and expensive procedure as compared to Coomassie Blue. Silver staining can result in high backgrounds; in addition, it stains not only proteins, but also DNA, lipopolysaccharides, and polysaccharides.

Different procedures have been described for detection of radioactive proteins separated on gels, which include autoradiography, fluorography and liquid scintillation counting. These methods are far more sensitive than staining methods for unlabeled proteins. It is remarkable that incorporation of the isotope does not alter the biological or enzymatic properties of proteins, nor change their net molecular charge. (38,39) The immunological methods for direct detection of proteins in a gel have now been superseded by the immunoblotting technique. (38) Immunoblotting, as well as the techniques for detection of enzymes following gel electrophoresis, are described in sections 4.2 and 4.4, respectively.

3.2 Isoelectrofocusing

This powerful technique is based on the electrophoretic separation of proteins according to their isoelectric points along a continuous pH gradient. Two major forms of IEF are presently used: conventional IEF utilizing CAs, namely CA/IEF, and IEF in an IPG. (39–43) CAs (known under different trade names such as Ampholine®, Pharmalyte®, Biolyte®, and Servalyte®) are synthetic amphoteric buffers – the oligoamino and oligocarboxylic acids – used to generate and stabilize the pH gradient over the pH range 3–10. The CA/IEF method is usually performed on a polyacrylamide matrix; however, for separation of very large proteins, agarose is preferable. The protein mixture is placed on a gel containing the CA buffers. When the electric field is applied, the small ampholytes migrate to their pI points, forming a continuous pH gradient in the gel, whereas the larger sample proteins begin a slower migration directed by the initial pH environment. Finally, each protein molecule reaches its isoelectric point within the established pH gradient. (39) Special procedures have been adopted to improve the performance of this technique. (39,41,45) These include addition of specific amphoteric compounds (good and bad spacers) to a given pH interval for local flattening of the pH gradient. Good spacers focus into a narrow zone and require low concentrations to induce a pronounced flattening of the pH curve around their own pI. Poor spacers are used in high concentrations and form a broad plateau in their pI region. Another way to improve the separation consists of subfractioning of the carrier buffers into narrow pH cuts – commercially available ranges span two or more pH units, and the technologies for preparation of the narrower pH cuts have been developed.

The most serious limitations of conventional IEF include cathodic drift of the pH gradient, uneven conductivity, and protein precipitation at the pI value. Some of these problems have been solved with the development of IPG. (23) In contrast to CA/IEF, in the IPG technique
the IPG are generated prior to the electrophoretic step by casting a gradient gel with the aid of a two-vessel gradient mixer. The buffers, termed Immobins™ (Pharmacia), represent eight weak acrylamide derivatives containing either carboxyl or tertiary amino groups, supplemented by one strongly acidic and one strongly basic derivate. During polymerization these buffering species are covalently attached and immobilized via vinyl bonds to the backbone polyacrylamide, thus providing reproducible and indefinitely stable pH gradients. The protein mixture is placed on a gel with a preformed IPG; when the electric field is applied, the sample molecules migrate to their pI regions. Receipts have been calculated for the generation of narrow, ultranarrow and extended pH gradients.\textsuperscript{(39,41,42)}

The protocols for casting polyacrylamide gels and the electrophoretic procedures used in IEF are described elsewhere.\textsuperscript{(39)} Usually, the polyacrylamide composition varies from 7%T and 5%C to 4%T and 2.5%C. Commercial precast Immobiline™ gels are now available. The major problem common for both CA/IEF and IPG is the precipitation and smearing of proteins near their pI. To cure this problem, IEF is performed in the presence of urea (6–8 M) and nonionic or zwitterionic detergents.\textsuperscript{(39)} To cure this problem, IEF is performed in the presence of urea (6–8 M) and nonionic or zwitterionic detergents. Encouraging results have been obtained when using as additives the nondetergent sulfobetains and a mixture of sugars and taurine.\textsuperscript{(43)}

The equipment for CA/IEF and IPG is similar to that of PAGE.\textsuperscript{(39)} Gel rod and vertical or horizontal slab gel systems are available (from LKB, Bio-Rad, and Pharmacia). The methods used for detection of proteins separated by IEF are also essentially the same as those for PAGE.\textsuperscript{(38,39)} Amphotolites should be removed prior to Amido Black staining [by soaking the gel in 10–15% trifluoroacetic acid (TFA)].\textsuperscript{(38)} The IPG-separated gels give strong backgrounds; therefore, in this case, medium-sensitivity stains are used.\textsuperscript{(39)}

3.3 Two-dimensional Electrophoresis

2D electrophoresis methods are designed to separate complex polypeptide mixtures on the basis of a different molecular property in each dimension.\textsuperscript{(47)} Typically, the most common 2D techniques utilize separation of proteins on the basis of charge by using IEF in the first dimension, and on the basis of molecular mass by using SDS/PAGE in the second dimension. The first dimension is performed by employing the CAs or IPG (these techniques are discussed above). The CA/IEF is usually carried out by using cylindrical gels in capillary tubes as described elsewhere.\textsuperscript{(38,44)} One of the major problems of this technique is protein–ampholyte interactions which cause the artificial spots on 2D maps. The other problem is cathodic drift, which leads to pH instability and loss of basic proteins from 2D maps. Therefore, for the analysis of basic proteins, nonequilibrium pH gradient electrophoresis (NEPHGE) has been developed.\textsuperscript{(45)} In this technique the polarity of the IEF apparatus is reversed – the sample is applied at anode, and the basic proteins migrate towards the basic end of the gel. Short time runs are used to avoid the gel running to equilibrium. Under these conditions the separation of proteins occurs on the basis of protein mobility in a rapidly-forming pH gradient. As the more acidic proteins are absent from the resulting 2D patterns, a combination of 2D patterns using equilibrium IEF and NEPHGE is helpful.

The introduction of IPG has provided a solution for pH instability occurring in conventional IEF. However, when using IPG for the first dimension in 2D separations, difficulties have been found in elution and transfer of proteins from IPG gels to the second-dimension SDS/PAGE gels (due to the presence of fixed charges on the Immobiline™ matrix leading to increased electroendosmosis). This problem has been overcome by the development of a special standardized protocol: IPG gels on GelBond PAG™ support films are dried, cut into strips, and rehydrated in urea and nonionic or zwitterionic detergents.\textsuperscript{(46)} Studies have also been carried out to optimize the pH gradients, because the narrow and ultranarrow pH gradients were not generally suitable for 2D separations.\textsuperscript{(47)} Receipts are now available for producing wide pH gradients (pH 2.5–11), which can be effectively applied in 2D electrophoresis.\textsuperscript{(48)} However, as the analysis of 2D maps obtained using wide-range IPG is difficult, the pH gradients spanning 3–4 pH units are commonly employed.

The second dimension is usually carried out by the Laemml technique\textsuperscript{(9)} using polyacrylamide of single or gradient concentration. The cylindrical IEF rod gel or IPG gel strip (bonded to plastic supports) is usually cemented on the top of the vertical SDS/PAGE slab gel with agarose. Using horizontal SDS/PAGE systems, the IPG strip is transferred on to the surface of the stacking gel.\textsuperscript{(44)}

Although 2D separations are usually carried out by combining IEF with SDS/PAGE, other 2D systems are used for the separation of some types of proteins, such as histones or ribosomal proteins. These include discontinuous PAGE in the first dimension followed by continuous PAGE in the second, both dimensions containing urea; acid–urea PAGE in the first dimension with Triton–acid–urea PAGE in the second; acid–urea PAGE in the first and SDS/PAGE at high pH in the second dimension.\textsuperscript{(44)}

Computerized systems designed for quantitative 2D gel analysis are now available. World Wide Web sites for 2D gel databases and imaging software developers are listed elsewhere.\textsuperscript{(49)}
3.4 Peptide Mapping

Peptide mapping is obtained by breaking down proteins into a number of peptide fragments in a specific and controlled manner, separating the peptide mixture, and then comparing the separation pattern with that of standard proteins treated in the same way.\textsuperscript{30} This can be done in many ways, by utilizing different protein fragmentation and separation techniques. Protein fragmentation can be accomplished enzymatically by proteases (such as trypsin, pepsin, or chymotrypsin) or chemically by employing chemical cleavage reagents (such as cyanogen bromide, hydroxylamine or N-chlorosuccinimide). For the separation of cleaved peptides the techniques of 1D or 2D electrophoresis, capillary zone electrophoresis, and either reversed-phase (RP) high-performance liquid chromatography (HPLC) or ion-exchange HPLC are generally used.

The utility of PAGE for peptide mapping was demonstrated in 1977 by Cleveland et al.\textsuperscript{20} SDS/PAGE was applied both for purification of proteins from complex protein mixtures, as well as for subsequent analysis of the enzymatically cleaved peptides. The pattern of peptide fragments obtained was characteristic of the protein substrate and the proteolytic enzyme. Although at the present time RP/HPLC is the most popular method for separation of small peptides, peptide mapping by gel electrophoresis is still widely used.

Three different strategies are currently applied for the fragmentation of proteins separated by gel electrophoresis: elution of proteins from the gel with subsequent fragmentation in solution; direct digestion of the protein in the gel; electrolabting of proteins on to supporting membranes and fragmentation on a membrane.\textsuperscript{51} (Procedures for elution and electrolabting are described in sections 4.2 and 4.7.) Optimization of the cleavage conditions is especially important for peptide mapping studies. The commercially available proteinases vary in activity depending on their specificity and purity, upon the nature of substrate proteins, as well as on the temperature and pH. Thus, in many cases, preliminary experiments are required in order to establish the optimal hydrolysis conditions. Generally, complete fragmentation produces small fragments whose separation is more difficult, even when using high-resolution RP/HPLC. Partial proteolysis with a considerable proportion of larger peptides is often desirable, especially when using SDS/PAGE slab gel as a mapping gel. First, small peptides may be poorly resolved and run close to the buffer front. Second, they are poorly fixed and stained in the gel, and may be washed out. Therefore, in many instances it is also advisable to use chemical cleavage agents that target the low-frequency residues (Met or Trp). Use of the Tris–Tricine–SDS system\textsuperscript{33} is preferable (instead of the Laemmli technique\textsuperscript{69}) by allowing separation of the fragments of a lower molecular mass.

Separated proteins can be localized using the standard detection methods used for gel electrophoresis, namely by autoradiography or fluorography when the radioactively labeled proteins are run, or by using staining techniques for the unlabeled proteins (e.g. Coomassie R-250 or G-250 or silver staining).\textsuperscript{37,38,50}

During the 1990s the importance of peptide mapping has increased due to the combination of this technique with amino acid sequencing and mass spectroscopy of peptide fragments (section 4.3).

3.5 Immunoelectrophoresis

Immunoelectrophoresis is the procedure in which proteins and other antigenic substances are characterized by both their electrophoretic migration in a gel (usually agarose) and their immunological properties. In classic immunoelectrophoresis\textsuperscript{31} proteins are first separated by zone electrophoresis; antiserum is then placed in the central slot, and proteins are allowed to diffuse to the gel. Proteins are precipitated by their antibodies during diffusion; the precipitation lines are formed at positions where antigen to antibody ratio is optimal. In cross-immunoelectrophoresis\textsuperscript{16} the protein sample is first subjected to gel electrophoresis in agarose, and then the separated proteins are driven into the gel containing antibodies by an electric field applied at right-angles to the initial separation. When a sufficient antibody is present the precipitates are formed, and the area enclosed by the precipitate is proportional to the amount of antigen. A major advantage of this technique is its potential for identification and resolution of a complex mixture of proteins. In rocket immunoelectrophoresis\textsuperscript{15} antigen is electrophoresed in agarose gel containing a specific antibody. This results in the formation of a long rocket-like immunoprecipitate; the height of the rocket correlates with the amount of antigen, thus allowing quantification of a specific protein. Various modifications of this technique have been developed, such as fused rocket immunoelectrophoresis, line immunoelectrophoresis, and intermediate gel technique. The techniques are simple and inexpensive; some have gained wide application in clinical laboratories. The equipment and the procedures for immuno-electrophoresis techniques are described elsewhere.\textsuperscript{52}

4 MAJOR APPLICATIONS

4.1 Determination of the Molecular Mass of Proteins and Polypeptides by Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis

PAGE can be used for determination of the molecular size of native, as well as denatured proteins. In the
case of native proteins, where separation occurs on the basis of differences in size and charge, the $M_r$ estimation technique relies on a mathematical canceling of charge effects following measurements of protein mobility in gels of different concentration. This is done by constructing the Ferguson plot, a plot of $\log_{10}$ relative mobility ($R_f$) versus gel concentration – when %C is kept constant, a linear relationship can be obtained. The slope of the line is the retardation coefficient, $K_r$, which is a measure only of molecular size. A linear relationship between $K_r$ and molecular mass is established, thus allowing construction of standard curves for determination of the $M_r$ of native proteins. However, this method is only valid if the standard proteins used to generate the calibration curves have the same shape as the unknowns.

In an alternative approach for the $M_r$ estimation, the differences in molecular charge are cancelled chemically. Proteins are treated with the anionic detergent SDS and then separated by SDS/PAGE by using the common Laemmli method. The SDS binds to proteins at an approximately constant ratio (1.4 g SDS per gram of protein), that masks the intrinsic charge of polypeptide chain and forms SDS–protein complexes having essentially identical densities of negative charge. As SDS eliminates charge density differences amongst proteins, migration of the polypeptides in polyacrylamide gels depends only on their size and not on their charge. Under these conditions, a plot of $\log_{10}$ polypeptide $M_r$ versus $R_f$ reveals a linear relationship over a certain range of $M_r$. Thus the appropriately selected proteins can be used as markers for the construction of a standard curve for the $M_r$ estimation of the denatured proteins. The $\log_{10}$ $M_r$ of standard proteins is plotted against $R_f$, and the $M_r$ of unknowns can be calculated on the basis of their $R_f$ values. In the discontinuous buffer system of Laemmli the linear relationship holds true for $M_r$ values from 12 000 to 45 000 on 15% polyacrylamide gels, and from 16 000 to 60 000 on 10 and 5% gels. The commonly used $M_r$ markers are commercially available (Sigma, Bio-Rad, Amersham).

As a linear relationship between $M_r$ and mobility is essential for accurate $M_r$ estimation, precautions should be taken to ensure maximal SDS binding in order to overwhelm the intrinsic charge of the polypeptide. It is therefore important to use an excess of SDS to polypeptide of at least 3:1. An excess of thiol reagent, usually β-mercaptoethanol or DTT, is needed to break disulfide bridges, which otherwise would prevent saturation of polypeptide with SDS.

The behavior of SDS-treated proteins can be analyzed by using Ferguson plots. Ideally, the intercept at 0%T, which is the apparent relative free mobility $Y_0$, could be identical for all SDS–polypeptide complexes having identical charge densities. In fact, many proteins behave “normally”, i.e. they approximate this situation. However, some proteins (glycoproteins, very basic or very acidic proteins, small peptides) behave anomalously by demonstrating markedly different $Y_0$ values even in an excess of SDS and thiol reagent.

Significant improvement in the $M_r$ determination was achieved by using gradients of an increased acrylamide concentration (instead of the gels of uniform concentration). During electrophoresis in the gradient gels, proteins migrate until the decreasing pore size impedes further process. The SDS/PAGE of proteins in linear gradient gels revealed a linear relationship between $\log_{10} M_r$ and $\log_{10}$ polyacrylamide concentration. Thus, with a suitable set of standard proteins, calibration curves can be constructed from which the $M_r$ of sample protein may be estimated (Figure 1). The $M_r$ range available for $M_r$ estimation depends on the conditions of gradient used: $M_r$ 14 000–33 000 in a linear gradient from 7 to 25%T (1%C); $M_r$ 14 000–210 000 in 5–20%T (2.6%C); $M_r$ 13 000–950 000 in 3–30%T (8.4%C). When compared with the uniform concentration gel, the gradient gels give sharper bands and allow the analysis of proteins over a wider $M_r$ range. Furthermore, glycoproteins and

some proteins (such as papain, lysozyme, and ribonuclease) which behave anomalously in uniform concentration gels, demonstrate normal behavior in the gradient gels.\(^{(54)}\) In general, gradient gels are especially useful in the study of complex mixtures of proteins varying significantly in their molecular sizes. However, when the proteins of interest are within a narrow \(M_r\) interval, uniform concentration gels may be superior.

Special SDS/PAGE techniques have been developed for the determination of \(M_r\) of small peptides, because the standard SDS/PAGE method\(^{(50)}\) failed to resolve or provide useful size estimates for peptides below \(M_r\) 12 000. Swank and Munkres\(^{(31)}\) demonstrated that inclusion of 8 M urea in the continuous buffer system and the increase in the proportion of cross-linker was effective in obtaining a linear relationship between mobility and \(M_r\) over the \(M_r\) range 2400 to 17 000. The improved separation was obtained by the inclusion of urea in the discontinuous buffer system; this allowed the \(M_r\) estimation within the \(M_r\) range 2000–92 000.\(^{(55)}\) Hashimoto et al.\(^{(56)}\) utilized 10–18% gradient SDS gels in presence of urea (Table 1) which enabled good resolution of peptides down to \(M_r\) 1500. In general, these urea-containing systems were effective for separation of proteins and peptides. However, the presence of urea could cause band smearing of polypeptide bands of \(M_r\) above 40 000;\(^{(57)}\) in addition, other disadvantages of urea arise from its instability, as well as its crystalization at low temperatures. Thus, the nonurea SDS/PAGE techniques employing high molarity Tris,\(^{(57)}\) ‘Tris–Tricine,’\(^{(33)}\) and Tris–Bicine\(^{(34)}\) buffer systems have been introduced (Table 1), allowing separation of proteins and peptides ranging from \(M_r\) 1000 to 100 000, and estimation of their \(M_r\) over this broad \(M_r\) range (Figure 2).

Although the rapidly developing methods of mass spectroscopy permit more precise determination of the \(M_r\) of proteins and peptides as compared with the electrophoretic techniques, the latter continue to play an important role in different fields of biochemical research as they are simple, rapid and inexpensive.

the support membranes has become one of the most popular techniques in protein analysis. The electrophoretic transfer of proteins from polyacrylamide gels to nitrocellulose sheets was first described by Towbin et al. This technique is now known as blotting (electroblotting) or Western blotting; when the electrotransfer is followed by antibody probing, the whole procedure is called immunoblotting. In general, introduction of the electroblotting technique essentially simplified the analysis of the electrophoresed proteins. The procedures for staining and destaining the blotted proteins are significantly shorter than in gels. The support membranes are easier to handle than the polyacrylamide gels; Western blots can be dried and stored for long periods prior to further analysis. Use of an appropriate blotting matrix allows multiple probing, i.e. examination of a single blot with several different detection systems. As a result, the immunological detection of proteins in gels is now almost completely replaced by immunoblotting. Finally, electroblotting has found especially wide application in amino acid sequencing and mass spectral analyses of proteins and peptides (section 4.3).

Various electrophoretic techniques of 1D and 2D electrophoresis are employed in Western blotting. Although electrophoresis is often carried out under denaturing conditions involving heat, reducing agents, SDS, and urea, which can reduce subsequent immunological activity, the experience usually shows no difficulties in the immunological detection of proteins. It is possible that the residual activity is sufficient to be detected by the sensitive methods used. It is also possible that in some cases the immunological activity is unaffected or even enhanced under the dissociating conditions.

4.2.2 Support Membranes

Among the variety of support matrices introduced in Western blotting the nitrocellulose membranes first applied by Towbin et al. are still most widely used and are available from different suppliers (Schlecher & Schuell, Millipore, Amersham International, Bio-Rad). Nylon membranes (e.g. Zetaprobe from Bio-Rad, Hybond N from Amersham) have the advantage of being stronger and of higher binding capacity than nitrocellulose, but have the limitation of a high nonspecific background with general stains (Coomassie Blue or Amido Black). Another type of supporting membrane includes diazo-modified papers; as the proteins are covalently bound to these matrices, a diazotized paper may be useful when a number of detection methods have to be applied sequentially to the same membrane. However, the diazotized paper matrices have lower binding capacity, they must be activated prior to their use, and are incompatible with the commonly used transfer buffers containing glycine (due to its interaction with diazo groups). At present, chemically stable PVDF membranes compatible with general protein stains and immunodetection methods are widely used (Millipore, Bio-Rad). Due to their chemical stability, the PVDF membranes have gained especially widespread application in amino acid sequence and mass spectral analyses (section 4.3).

4.2.3 Equipment and Transfer Buffers

Equipment for the electrotransfer of proteins is available commercially and includes tank-type apparatus (Bio-Rad, Hoeffer Scientific Instruments, Novex) and semidry electroblotting systems (Bio-Rad, Hoeffer Scientific Instruments, Millipore). The electric field is applied transversely to the gel, allowing migration of proteins from the gel to the membrane. In tank-type apparatus the gel–membrane sandwich is immersed in a buffer tank. The sandwich is prepared for sequentially placed layers: (1) porous pad (foam sponge or ScotchBrite scouring pad); (2) Whatman paper, 3MM; (3) gel; (4) membrane; (5) Whatman paper, 3MM; (6) porous pad. When the SDS gels are electroblotted at neutral or alkaline pH,
the membrane should face the anodic side. In contrast, under acidic conditions when the proteins behave as cations, the membrane should be at the cathodic side. The typical buffer systems used are 20 mM Tris–150 mM glycine (pH 8.3), 7.5 mM Tris–1.2 mM boric acid and 25 mM sodium phosphate (pH 6.5); methanol (20%) is often added because it minimizes the swelling of the gel during blotting and increases the binding capacity of nitrocellulose to protein.(37) As methanol reduces protein elution from the gels, 0.1% SDS is often incorporated in the transfer buffer to enhance the efficiency of elution. Another commonly employed transfer buffer is 10 mM 3-(cyclohexylamino-1-propanesulfonic) acid (CAPS)–10% methanol (pH 11) which is used for the electro-transfer of proteins to PVDF™ membranes.(51) The buffer system 25 mM Bicine–25 mM Bistris, pH 7.2, containing 1.02 mM ethylenediaminetetraacetic acid (EDTA) and 20% methanol, is recommended for electro-transfer of proteins to nitrocellulose, as well as to PVDF™ in Novex Western Transfer Apparatus, Model X Cell II.

In semidry transfer apparatus the voltage is applied through filter papers soaked in transfer buffer. Due to the high field strength, the transfer is rapid. It requires less transfer buffer than tank-type apparatus. Another advantage of semidry apparatus is the possibility of using multiple buffers by soaking filter papers in different solutions. As alkaline pH and SDS favor protein elution from gel, whereas methanol and acid pH favor their adsorption on membrane, the appropriate asymmetrical disposition of methanol, SDS, and pH on each side of the membrane can be extremely useful.(58–61) Highly efficient semidry transfer has been achieved by creating a stable pH boundary between the two faces of membrane – basic on the gel side (in the presence of SDS), and acidic on the membrane side (in the presence of methanol).(61)

4.2.4 Detection Systems

Once the proteins are electroblotted, they can be immunodetected by specific antibodies. As antibodies can be bound nonspecifically by the supporting membrane, the nonspecific binding sites should be blocked. Blocking is usually performed by incubating the membrane with bovine serum albumin or skim milk solution for several hours. The immunodetection procedure includes the following steps: incubation with the specific first antibodies, washing away the excess of unreacted antibodies, and incubation with second labeled antibodies directed against the first antibodies. Finally, the excess of unreacted antibodies is washed out, and the bound second-labeled antibodies are detected. In early studies radioiodinated and fluorescently labeled second antibodies were used and detected with autoradiography and ultraviolet illumination, respectively. Most studies are now carried out by enzyme labeling, usually horseradish peroxidase (HRP) and alkaline phosphatase (AP), which are visualized by converting suitable soluble substrates into colored precipitates in the presence of special color development reagents (such as 3′,3′-diaminobenzidine or 4-chloro-1-naphthol). The advantage of the AP method is that the colored reaction product does not fade, in contrast to the HRP method. A variation of these methods is utilization of biotinylated antibodies that are recognized by avidin or by streptavidin labeled with an enzyme or fluorescent tag. Recent progress has been made with the introduction of the enhanced chemiluminescence (ECL) Western blotting technique which is a light-emitting non-radioactive method for detection of the HRP-labeled antibodies. The commercially available substrate reagents include luminol/enhancer solution and a stable peroxidase buffer solution (Amersham, Pierce). When the blot containing the antigen bound to the HRP-labeled antibody is incubated with the mixture of these solutions, luminol is oxidized, resulting in emission of light which can be detected by exposure to autoradiography film. The recently developed ECL substrate systems (Pierce) allow detection of proteins at mid-femtogram and even at low femtogram levels.

4.3 Electrophoretic Separation of Complex Mixtures of Proteins and Peptides for their Chemical Analysis – Microsequencing and Mass Spectrometry

4.3.1 General

With the development of highly sensitive automated protein sequencing procedures in the 1980s(24–27) and after the introduction of MS for examination of proteins in 1985,(62,63) gel electrophoresis emerged as an extremely useful protein sample micropreparation technique for the subsequent determination of its amino acid sequence and mass. At the present time electrophoretic separation and purification of proteins remains one of the most widely used approaches, despite the recent progress made in the protein separation field, especially in development of new HPLC systems and capillary electrophoresis. There are three reasons for the popularity of gel electrophoresis:

- electrophoretic separations are reproducible and provide high resolution of proteins and peptides by appropriate selection of either 1D or 2D techniques;
- electrophoretic techniques are simple, rapid and inexpensive;
- proteins separated on gels can be blotted on the supporting membranes compatible with sequencing
and mass spectral procedures that in many instances facilitate protein analysis.

It is notable that the amount of purified proteins obtained by employing analytical scale gels is sufficient for their further analysis with highly sensitive microsequencing and mass spectral techniques, allowing detection of proteins and peptides at a picomole and subpicomole level (the latter techniques are described in the article Matrix-assisted Laser Desorption/Ionization Mass Spectrometry in Peptide and Protein Analysis).

The electrophoretic purification of proteins used in amino acid sequencing and MS studies is commonly conducted by employing Tris–glycine(\textsuperscript{9}) or Tris–Tricine(\textsuperscript{33}) SDS/PAGE (sections 3.1 and 4.1). The 2D separations, which include IEF with IPG gels in the first dimension and SDS/PAGE in the second, are also widely used (section 3.2). Precautions should be taken to avoid the gel electrophoresis-induced modifications of proteins which could affect mass determination by MS. Some of these modifications are due to incomplete polymerization of acrylamide. Usually more than 30 mM of free acrylamide remain, which may form covalent adducts with cystein during gel electrophoresis. In addition, oxidation of methionine residues can occur, probably due to the presence of residual persulfate in the gel. Other modifications include formation of oxidized cystein–acylamide and cystein–2-mercaptoethanol adducts. In order to prevent these undesirable modifications, several reagents are in use, such as mercaptoacetic acid, 3-mercaptopropanoic acid (in Tris–Tricine SDS/PAGE), glutathione or sodium thioglycolate (in SDS/PAGE), or free cystein (for IPG gels).\textsuperscript{58,64}

4.3.2 Applications in Amino Acid Sequence Analysis

After electrophoresis, subsequent processing of the sample depends on whether N-terminal or internal amino acid sequence analysis is required. For N-terminal sequencing, the gel-separated proteins can be electroblotted on the supporting membranes (section 4.2) or electroeluted (section 4.7). Electroblotting is commonly preferred over electroelution because fewer manipulations are required.\textsuperscript{24,25,58,65} After the introduction of PVDF\textsuperscript{TM} as a sequencing substrate in 1987,\textsuperscript{24} different types of PVDF\textsuperscript{TM}-based membranes were developed and applied for amino acid sequencing. High-retention PVDF\textsuperscript{TM} membranes such as Immobilon-PSQ\textsuperscript{TM} (Millipore), ProBlot\textsuperscript{TM} (Applied Systems, Inc.), and Trans-Blot PVDF\textsuperscript{TM} (Bio-Rad) are preferably over low-retention membranes, when the N-terminal sequence is required.\textsuperscript{58,65} The major problem in protein sequencing is the N-terminal blockage. In fact, about 80% of cellular proteins in eukaryotes are blocked at their N-termini; in most cases these are acetyl, formyl, and pyroglutamyl groups. Techniques for deblocking have been developed;\textsuperscript{65} however, they are not always effective and therefore internal sequence analysis may be needed. For internal sequencing, the gel-separated proteins are cleaved enzymatically or chemically, and the cleavage products obtained are separated, usually by HPLC or gel electrophoresis, for their further analysis. The strategies applied for generation and isolation of peptides from the gel-separated proteins are the same as those described for peptide mapping (section 3.4). First, proteins can be electroeluted from the gel and then digested. Second, proteins can be in-gel digested and then the resulting peptides are eluted. Third, proteins can be blotted on to the membrane and then either eluted from membrane and digested, or digested on the membrane. The major advantage of using blotting membranes is easy removal of salts and detergents from proteins prior to their sequencing. However, for proteins of low blotting efficiencies, in-gel digestion or elution plus digestion can be recommended. In any case, SDS removal is of special importance because it can reduce the extent of enzymatic digestion, as well as interfere with the subsequent RP/HPLC separation of the resulting digest. When the proteins are eluted from the SDS gels, SDS is removed by trichloroacetic acid (TCA) or acetone precipitation; however, these procedures may be complicated when the protein concentration is too low or the SDS concentration is too high.\textsuperscript{66,67} However, SDS removal from the PVDF\textsuperscript{TM}-blotted proteins is simple and can be achieved by washing the membrane by methanol or acetone or during staining/destaining procedures.\textsuperscript{64} In many instances the low-retention membranes (such as Immobilon-P (Millipore) or Westtran\textsuperscript{TM} (Schleicher and Schuell, Inc.)),\textsuperscript{58,65} as well as nitrocellulose (Schleicher and Schuell, Inc.)\textsuperscript{26,66,69} have been found suitable for internal sequencing. Good recoveries have been obtained with membranes having attached charged groups, such as carboxymethylnitrocellulose\textsuperscript{68} and Immobilon-CD.\textsuperscript{58,70}

4.3.3 Applications in Mass Spectral Analysis

Utilization of MS for accurate mass determination of the gel-separated proteins and peptides has gained increasing popularity. Although SDS/PAGE is still widely used for $M_r$ estimation, this method has an accuracy of about ±10\%.\textsuperscript{64} (section 4.1). In contrast to electrophoretic techniques, the high accuracy of MS techniques allows detection of mass differences between protein isoforms; MS analysis is also able to provide information on post-translational modifications of
protein, and makes possible determination of the number of proteins comigrating in a band or spot in the gel.

Both MALDI/MS and ESI/MS have been found useful for the analysis of intact proteins electroeluted from gel, and for proteins electroblotted on PVDF membranes. Removal of SDS is essential in these studies because it inhibits ionization in both MALDI/MS and ESI/MS. (29,30)

These MS techniques are applied to the analysis of enzymatic digests generated from gel-separated proteins. In general, the common methods of electroelution, or in-gel or on-membrane digestion are applicable to MS. However, most protocols used for in-gel digestions utilize neutral detergents (Tween-20™, Triton X-100™, NP-40™) to enhance the recovery of peptides. The presence of neutral detergents poses a significant problem in MS analysis in that they suppress ionization in MALDI and can interfere with ESI/MS analysis. Thus, several modifications have been introduced to eliminate the use of neutral detergents in the in-gel digestions. (64) The protocols used for on-membrane digestion usually employ additives prior to the enzymatic digestion in order to prevent absorption of enzyme to membrane (PVDF™-based membranes and nitrocellulose). Addition of polyvinylpyrrolidone, average Mw 40,000 (PVP-40) has enabled generation of samples compatible with MALDI/MS and with liquid chromatography (LC)/MS (ESI/MS coupled with HPLC). Triton X-100™ was effectively utilized to enhance the recovery of peptides from nitrocellulose and high-retention PVDF™; however, the above-mentioned problems in MS analysis were observed when using this neutral detergent. Some other useful modifications to increase the peptide recovery have been described, such as reduction and alkylation prior to digestion or addition of polyvinylpyrrolidene, average Mw 360,000 (PVP-360). (64) The MS-compatible protocols employing the charge-modified membranes and allowing good recovery of peptides have also been reported. (64,70,71)

Accurate mass determination of gel-separated peptides by MALDI/MS, ESI/MS, and LC/MS has been found useful with peptide sequencing in the peptide-mapping studies. In fact, peptide mass data obtained by MS analysis can provide a unique fingerprint for that protein. Thus, when using specific cleavage rules, the peptide mass data obtained can be interpreted by consulting the existing protein sequence databases. These peptide-mass databases can be searched by using the experimentally obtained peptide masses to identify and characterize the protein; different computer programs have been developed and are now available commercially. (72)

4.4 Detection of Enzyme Activity Following Gel Electrophoresis

4.4.1 General

The detection of enzyme activity following gel electrophoresis is a popular technique in the analysis of crude enzyme preparations. There are two different approaches to the electrophoretic separation of enzyme proteins. Separation can be accomplished under the non-denaturing (native) conditions (6,36) that retain their enzymatic activity. Alternatively, electrophoresis can be carried out under denaturing conditions, such as in the presence of SDS and disulfide cleavage agents. (9) In this case, a renaturation step that includes SDS removal is usually needed after the electrophoresis; however, some enzymes retain activity even in the presence of SDS. (73,74) Although in some instances SDS/PAGE was found to be unsuitable for the detection of protein activity due to its irreversible denaturation, (75) SDS/PAGE has been successfully applied to the detection of a large number of different proteases (such as trypsin, chymotrypsin, collagenase, pronase, endopeptidase I, carboxypeptidases A and B), protein phosphatases, kinases, peroxidases and others. The popularity of SDS/PAGE in these studies is due to the high resolution power and reproducibility of this technique.

The different factors that influence the renaturation of enzymes separated by SDS/PAGE should be taken into consideration. These include the preparation of a sample prior to electrophoresis, the electrophoretic conditions, and the postelectrophoretic treatment. Some enzymes are successfully renaturated following the classical sample preparation procedure of heating the SDS–protein sample at 100 °C under reducing conditions. In other cases, however, much milder conditions are needed to retain the enzymatic activity (for example by preparing the SDS–protein complexes at lower temperature, by avoiding the use of thiol reducing agents, or by including the carrier proteins). Some studies include exogenous proteins in the gel polymerization mixture; it has been supposed that the included proteins act either as molecular chaperones, or as absorbents of heavy metals or other toxic materials. (74) Different strategies have been applied for SDS removal from the gel-separated proteins. These include washing the gel in aqueous buffers in absence or in presence of anion exchange resins, (76) adding the organic solvents (77,78) or by using competing nonionic detergents (79,80) or chaotropic agents (e.g. urea or guanidine hydrochloride). (81–83)

4.4.2 Enzymatic Activity Assays

Different approaches are used for assaying the enzymatic activity. The assay can be carried out in situ on the gels,
or following the extraction of proteins (by diffusion or electroelution), or after electroblotting on to membranes (nitrocellulose or PVDF\(^{86}\)). Removal of proteins from gel matrices allows easy application of different protocols for regeneration of enzymes, as well as for detection of the enzymatic activity. However, the extraction procedures are laborious and time-consuming; they can also lead to loss of resolution because slight differences in enzyme migration can be missed. The resolution of electrophoretically separated proteins can be preserved by electroblotting. However, the limitations of using this technique become apparent in enzyme detection assays in which the reaction products are soluble and are of low \(M_r\), and hence cannot be confined to the region in which they were produced. Electroblotting techniques have been utilized for the detection of protein kinases which autophosphorylate and therefore act by themselves as the immobilized substrate/product; when \(^{32}\text{P}\) ATP (adenosine triphosphate) is used as the cosubstrate, the radiolabeled autophosphorylated protein kinases can become visible. The detailed description of these assays, their application to different enzymes classes, and numerous references are given in review articles.\(^{73,74,85}\)

### 4.5 Gel Electrophoresis in Protein Conformation and Quaternary Structure Studies

Protein folding is one of the basic issues in the biochemistry of macromolecules. Under different denaturing conditions, such as rise in temperature, variations in pH, or addition of denaturants, proteins are unfolded and their native secondary and tertiary structure is lost. Unfolding transitions can be studied by any of the physicochemical techniques that are sensitive to changes in protein conformation.\(^{86,87}\) The denaturant-induced unfolding leads to a significant increase in dimensions of polypeptide. In 1979, Creighton first applied the technique of transverse urea-gradient electrophoresis to monitor the denaturant-induced unfolding.\(^{88}\) In this technique, protein is electrophoresed in a direction perpendicular to urea gradient (usually from 0 to 8 M), where the macromolecules are exposed to various urea concentrations at different positions of the gel. At the position where the concentration of urea is high enough to induce unfolding, the mobility of protein decreases due to the greater hydrodynamic volume of the unfolded form. After visualization of protein, the resulting electrophoretic pattern is interpreted as the unfolding curve. The analysis of the relationship between the transition rates from native to unfolded states and the electrophoretic patterns is described elsewhere.\(^{87–90}\)

As compared with other physicochemical methods used in protein folding studies,\(^{86,87}\) transverse urea-gradient electrophoresis is a simple and inexpensive technique requiring only small amounts of protein. It was also found useful to follow the changes occurring in quaternary structure, i.e. dissociation in urea of the oligomeric proteins into monomers, where transition to faster-migrating species occurs at a particular urea concentration.\(^{87,89,91–95}\) The dissociation may occur prior to or after unfolding; in some cases these two processes cannot be differentiated.

Different modifications to the basic technique have been described. In some studies both urea and Triton gradients were included;\(^{94}\) other authors used the urea gradient in presence of SDS.\(^{95}\) As the presence of different concentrations of urea may cause differences in the viscosity across the gel, the inverse gradient of the polyacrylamide concentration was used in some studies, e.g. 10–8%T, or 10–7.5%T for a 0–8 M urea gradient.\(^{91,92}\) In most cases, homogenous buffer systems (of alkaline or acid pH) were used; however, applications of discontinuous systems have also been described.\(^{97}\) For visualization of the electrophoretic patterns, general protein-staining techniques (e.g. Coomassie or silver staining) are useful when the analyzed sample contains a single purified
Protein. When the sample contains several different proteins or when the functional protein properties are to be examined, specific detection techniques such as immunoblotting or enzyme activity assay are employed. Detailed information on the preparation of gels, running conditions, and detection systems is available.\(^{(96, 97)}\)

Protein unfolding can influence not only changes in volume, but also the surface charge. In some studies,\(^{(87)}\) unfolding was followed by using IEF across the transfer urea gradient. Another useful electrophoretic technique was developed to monitor the conformational changes induced by heat denaturation. In this technique, first described by Thatcher and Hodson in 1981,\(^{(98)}\) a temperature gradient was applied in the direction perpendicular to the electrophoretic run by using an aluminum heating jacket clamped around a vertical polyacrylamide slab gel.

Numerous biochemical applications have demonstrated the ability of these techniques to distinguish subtle differences in the behavior of various isomers and mutant proteins, in the analysis of folding/unfolding pathways, and to examine the dissociation of multimeric proteins. These studies have been reviewed.\(^{(87, 90)}\)

### 4.6 Gel Electrophoresis in Protein Interaction Studies

Proteins are able to bind a large number of biochemical, organic and inorganic compounds; different electrophoretic techniques have been employed to study these interactions.

Interaction may occur between proteins and ions of the electrophoresis buffer media. This has been observed when using borate buffer systems – borate ions interact reversibly with protein, resulting in the appearance of two zones for a single protein. Generation of multiple-protein zones due to interaction of proteins with buffers containing carboxylic and amino acids has also been observed. In general, these effects are undesirable, because the resulting multiplicity of bands may be misinterpreted as inherent heterogeneity of protein. In some cases, however, such interactions may be beneficial; thus, borate ion binding to glycoproteins allowed extension of the semilog relationship between migration distance and \(M_r\) in SDS/PAGE.\(^{(99, 100)}\)

The technique of counterion electrophoresis was originally developed to study calcium binding,\(^{(101)}\) but it can also be applied to study protein interaction with other cationic or anionic ligands.\(^{(99)}\) In this technique, radioactive Ca ions (added to the anode reservoir) migrate up to the gel in the direction of cathode, whereas the protein (placed in the cathodic end) migrates down the gel where it binds calcium. The system reaches a steady state in which calcium is uniformly distributed, and the amount of bound calcium can be determined by subtracting the apparent baseline concentration from the total calcium concentration in the protein zone.

Transverse urea concentration gradient electrophoresis (section 4.5) has been employed to follow the dissociation of protein bound to small charged ligand complexes, where removal of the small ligand resulted in changes in the electrophoretic pattern.\(^{(102)}\)

IEF (section 3.2) has been effective in studying the binding of proteins with neutral molecules, such as oxygen or vitamin D. In these cases, the noncharged compounds affect the surface charge of binding protein and its pI.\(^{(100)}\)

The binding of proteins with detergents is widely exploited in electrophoretic studies. The best example is SDS electrophoresis, where the stoichiometric binding of SDS to proteins allows estimation of \(M_r\) for many proteins and peptides (sections 3.1 and 4.1). In contrast to SDS, neutral detergents bind to proteins in different amounts depending on even slight differences in their hydrophobicities. Small additions of neutral detergents to urea-containing gel media of IEF may result in pI shifts, thus permitting discrimination of minute differences in protein structure.\(^{(103)}\) Charge-shift electrophoresis\(^{(104)}\) is another example in which detergents are used in electrophoretic separations. Electrophoresis is carried out in the presence of nonionic detergents, and the resulting patterns are used as references; test runs are performed by adding cationic or anionic detergents. Depending on the charge of added detergent, amphipatic proteins display either anodal or cathodal shifts in their electrophoretic behavior. The immunoelectrophoretic techniques applied in these studies allowed identification of proteins in complex mixtures and provided information on the extent and nature of their interaction with detergents.

Affinity electrophoresis is applied to study protein interactions with different molecular mass ligands, such as lectins, enzymes, various binding proteins, and polysaccharides. The protein sample is electrophoresed under nondenaturating conditions in polyacrylamide gels (or occasionally in agarose) in the presence of ligands (free or immobilized) that interact with the protein. Under these conditions the mobility of protein is retarded as compared with a control run, i.e. in the absence of any ligand. The theory and measurements of the dissociation constants of the affinity interaction are described elsewhere.\(^{(38, 99, 100)}\)

Electrophoretic methods are especially useful in studying interactions within the quaternary structure. Application of transverse urea-concentration gradient electrophoresis in analysis of protein subunit dissociation/association is described in section 4.6. Another popular and simple approach in subunit analysis is a comparison of the electrophoretic profiles obtained by SDS/PAGE separations in the presence and absence of thiol cleavage agents (sections 3.1 and 4.1). In some studies a similar approach was taken by utilizing IEF; in this case, the pI of the subunits resulting from the
reduction of protein usually differs from that of intact protein.\(^{(100)}\)

The immunochemical techniques used to study antigen–antibody interactions are described in the previous sections. These include classic immunoelectrophoresis, rocket immunoelectrophoresis, crossed immunoelectrophoresis and other variations of these techniques (section 3.5), as well as immunoblotting (section 4.2).

The ligand-blotting technique is conceptually similar to immunoblotting. The electrophoresed proteins transferred to membranes can be recognized by their binding with different ligands: low-\(M_r\) components, such as \(^{45}\text{Ca}\), \(^{59}\text{Fe}\), \(^{14}\text{C}\)-phospholipids, iodinated proteins (e.g. insulin growth factor, tumor necrosis factor), and lectins conjugated with different reporter molecules have been reviewed.\(^{(100)}\) As in immunoblotting, 1D or 2D electrophoretic separations are applied. The binding capacity is retained when using SDS/PAGE, but may be lost in the presence of thiol cleavage agents.

### 4.7 Gel Electrophoresis in Preparation Small-scale Purification of Proteins

Despite recent progress in the technology of chromatographic separations, especially HPLC, simple and inexpensive PAGE remains one of the most popular techniques for small-scale purification of proteins and peptides. In many cases preparative electrophoresis of a crude protein sample provides a level of purity that would otherwise require multiple chromatographic procedures. Although various designs of electrophoretic equipment are commercially available for large-scale purification purposes, at present they are rarely used for the preparative work. First, the resolution is lower than for analytical gel electrophoresis. Second, the amounts of protein purified using analytical-scale gels are sufficient for their analysis by modern analytical techniques.

Proteins are recovered from gels in different ways. They may be extracted (eluted) from the gels or electroeluted. Alternatively, they can be electrotransferred on to membranes and then extracted. Elution from gels is possible following protein staining, but usually staining of gels reduces the efficiency of extraction. Different procedures have been described for localization of proteins in unstained gels.\(^{(37,38)}\) A simple protein localization in unstained gel is also possible using prestained molecular weight markers (Bio-Rad, Amersham); in this case, the electrophoretic mobility of the protein under study is determined by staining the gel in a preliminary run.

Buffers used in the extraction range procedures in most cases contain SDS (0.1%)\(^{(37,105)}\) or urea (4–8 M).\(^{(38)}\) The localized gel area is excised, and the gel slice is chopped and incubated in about three volumes of buffer overnight, stirring constantly. A repeated extraction is usually carried out the next day.

Electrophoretic elution can be performed using different devices, such as Electro-Elutor Model 422 (Bio-Rad) or Biodyalizer (Sialomed, USA). However, in many instances a more simple procedure is applied. The gel slice is transferred into a dialysis bag, which is then placed into a horizontal electrophoresis tank filled with elution buffer (e.g. 0.1 M sodium phosphate, 0.1% SDS (pH 7.4)),\(^{(37)}\) or 25 mM Tris, 192 mM glycine, 0.1% SDS (pH 8.3)\(^{(106–108)}\). In an electric field (20–200 V), proteins migrate out of the gel into the dialysis bag. Upon complete elution (2–8 h), the contents of the bag are centrifuged, the gel particles are removed, and the supernatant containing the eluted protein is collected.\(^{(37)}\)

In an alternative approach to recover protein from the gel matrix, proteins are electrotransferred to PVDF\(^{(37)}\) or nitrocellulose (section 4.2) and then extracted from the membranes with detergents or organic solvents.\(^{(109,110)}\) Use of volatile organic solvents, such as isopropanol, acetone-titrile, formic acid, or TFA, is especially recommended, because they are readily removed by Speed-Vac without the need for dialysis.

The purification of proteins employing the elution-from-gel technique requires a subsequent SDS removal step which is not simple to perform (SDS cannot be completely removed from proteins by dialysis). In contrast, SDS removal is not a problem when the blotted proteins are recovered from membranes. First, SDS is partially dissociated from the protein during electrotransfer due to inclusion of methanol in a transfer buffer; second, SDS can be removed from membranes during the staining/destaining procedure (sections 4.2 and 4.3). However, the limitation of extraction-from-membrane techniques is that the efficiency of extraction may depend on the \(M_r\) and nature of the blotted protein, thus the extraction conditions should be carefully optimized for the proteins under study.

Several techniques have been developed and applied to SDS removal following the elution of proteins from gels. In early studies, the use of ion exchange resins in the presence of urea was found effective for SDS removal.\(^{(111)}\) However, this procedure had to be followed by TCA precipitation of proteins or extensive dialysis to remove urea; this is not always suitable for the small amounts of proteins recovered from analytical-scale gels. The application of an ion-retardation resin (Bio-Rad, AG11A8) with aqueous buffers containing no chaotropic agents has been reported;\(^{(112)}\) however, this technique may not be appropriate for purification of insoluble hydrophobic proteins. A simple technique relying upon ion-pair extraction of SDS into a mixture of organic solvents (acetone, thiethylamine, acetic acid, and water, 85:5:5:5) and acetone precipitation of protein has been described.\(^{(113)}\) At
present, techniques based on acetone or TCA precipitation are widely used. However, they are efficient only at a protein concentration above 100 µg per milliliter and at SDS concentrations not higher than 0.05%. Thus, it might be necessary to reduce the SDS level by dialysis (especially after protein concentration by Speed-Vac) which is less appropriate if working with small amounts of protein. An SDS-removal technique based on dissociation of SDS–protein complexes in 50% acetonitrile–0.1% TFA solution has been reported, where proteins were purified by employing gel permeation chromatography on a Fractogel™ TSK HW-40 (F) column (Merck) in this aqueous organic solution. Although this technique is more complex than acetone or TCA precipitation methods, it allows the proteins to be recovered in a soluble state thus avoiding the problems associated with acetone or TCA precipitation.

The most common form of electrophoresis used for preparative purposes is SDS/PAGE. However, this technique may not be efficient enough when different proteins of similar M_r have to be separated. 2D electrophoresis is an extremely powerful separation technique allowing differentiation of proteins on the basis of pI (in the IEF dimension) and M_r (in the SDS/PAGE dimension; section 3.3). Combination of 2D electrophoresis with a blotting procedure is widely used as a sample preparation technique for subsequent chemical and immunochemical analysis (sections 4.2 and 4.3). Unfortunately, 2D electrophoresis is less suitable for preparative work when using elution from gel techniques. The loading capacity (sample volume or protein amount) is low, and the protein bands in the second dimension are not sharp (as compared with those obtained by 1D separations); this makes it difficult to obtain efficient protein elution from gels. A new protocol for micropreparative purification of proteins employing 2D separation has been reported, in which the protein mixture was separated by SDS/PAGE, blotted, and extracted from membranes. The material obtained from 10 blots was then subjected to 2D electrophoresis, thus significantly increasing the loading capacity of the sample.

Consecutive use of SDS/PAGE and chromatographic techniques, especially RP/HPLC, can be another useful approach in small-scale preparative separation of proteins. This approach combines the resolution power of analytical gels with the high separation speed of HPLC, and permits separation of proteins – first, on the basis of their differences in M_r, and, second, due to their differences in hydrophobicity. This technique has been developed and applied to the small-scale purification of amyloid A proteins and, for micropreparative separation of major acute-phase reactants of mice, the isomers of serum amyloid A (SAA1 and SAA2). In these studies, proteins separated by SDS/PAGE were electroeluted from the gels, purified from SDS, and applied to Vydac™ 214 TP54 RP/HPLC column (Alltech, USA).

Further improvements in the technology of 1D and 2D electrophoretic separations, and the development of new techniques combining gel electrophoresis and modern chromatography, could be promising for efficient purification and analysis of proteins and peptides.

**ABBREVIATIONS AND ACRONYMS**

- AP: Alkaline Phosphatase
- ATP: Adenosine Triphosphate
- Bicine: N,N′-Bis(2-hydroxyethyl)glycine

peptides were developed largely during the 1970s, aided in particular by the availability of optimized column packing materials for the separation of higher molecular weight proteins based on the use of wide-pore silica supports.\textsuperscript{14,15} These methods offered unrivaled advantages in terms of speed, resolution, sensitivity and recovery when used for the purification of small (low-micrograms level) quantities of biologically important compounds such as growth factors or their receptors from complex biological sources. The generation of column packing materials with alternative selectivities (e.g. RP, HI, anion-exchange, cation-exchange, size-exclusion, chromatofocusing, affinity) facilitated the development of high-resolution multidimensional methods, often resulting in high cumulative purification factors.\textsuperscript{60} However, conventional HPLC columns (e.g. 4.6-mm i.d. operated at flow rates of ca. 1 mL min\textsuperscript{-1}) typically resulted in peak volumes of ca. 1 mL, or even larger. The resultant sample concentrations (µg mL\textsuperscript{-1}) were not ideally suited to subsequent manipulations, and at such low concentrations losses due to non-specific adsorption on either the chromatographic support or associated equipment (syringes, sample vials, concentration membranes, etc.) were commonplace. Even when using volatile chromatographic solvent systems (e.g. trifluoroacetic acid (TFA)–acetonitrile (CH\textsubscript{3}CN), heptafluorobutyric anhydride (HFBA)–CH\textsubscript{3}CN, ammonium hydrogen carbonate) to allow subsequent sample concentration, poor recoveries were frequently observed after lyophilization.\textsuperscript{7–10} In addition, solvent evaporation was shown, in some cases, to result in chemical modification even when performed in an inert atmosphere.\textsuperscript{11} Attempts to reduce peak volumes by operating at lower flow rates were shown to be associated with poor recoveries of, in particular, more hydrophobic proteins.\textsuperscript{12,13}

Chromatographic theory suggested that the use of columns with smaller internal diameter (narrowbore, microbore or capillary columns) would enable samples to be recovered in reduced volumes at increased concentration. However, while microbore HPLC systems had been described previously for low-molecular-weight compounds, and had been shown to be associated with very high operating efficiencies,\textsuperscript{14,15} they had not been generally accepted because of perceived sample volume limitations (injection volumes of <1 µL), limiting their application when working with large-volume samples at low concentration. Fortuitously, proteins and peptides exhibit very large capacity factors ($k'$) on interactive supports below critical secondary solvent compositions,\textsuperscript{16} allowing large-volume samples to be loaded, and hence overcoming the perceived limitations.

### 2 PRINCIPLES OF MICROPREPARATIVE HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

#### 2.1 Chromatographic Principles

It can be shown that eluent peak volumes from chromatographic columns are directly proportional to the column length and inversely proportional to the square of the column diameter.\textsuperscript{17} Thus, if we compare a 4.6-mm i.d. column operated at a flow rate of 1 mL min\textsuperscript{-1} (a practical optimum for many chromatographic columns of these dimensions, as evidenced by a minimum in plots of linear flow velocity ($u$) against height equivalent to a theoretical plate (HETP) in the Van Deemter equation)\textsuperscript{18} with a 1-mm i.d. microbore column, the flow rate for the 1-mm i.d. column would need to be reduced by (4.6/1)\textsuperscript{2}, i.e. 21-fold, to approximately 50 µL min\textsuperscript{-1} to operate at the same linear flow velocity (Figure 1). Under such operating conditions, if the same mass of protein is loaded on to each column, and the chromatographic efficiency of each column is identical (high packing efficiencies can be achieved with microbore and capillary columns), then samples will be recovered from the microbore column in concomitantly reduced peak volumes (50 µL compared with 1 mL for a peak 1 min wide). For concentration-dependent detectors, this increase in sample concentration will give a directly proportional increase in the detection signal if the flow cell geometry is conserved. It has been shown that this predicted performance can be achieved in practice.\textsuperscript{16,19} Nanogram quantities of peptides and proteins can be readily detected using small-bore columns (Figure 2), with peak elution volumes of 100 µL or less.

#### 2.2 Resolution

Resolution is a function of both the packing selectivity and the efficiency with which the column has been packed. Therefore, columns of the same efficiency but of different dimensions operated under equivalent elution conditions (solvent composition, gradient profile, temperature and linear flow velocity) should give identical separations of complex mixtures. This has been shown in practice,\textsuperscript{16,19,20} and facilitates direct scale-up or scale-down of separation protocols using matched columns. There will be small differences in resolution/retention time not related to the columns themselves, but to instrumental variations mainly due to extra-column dead volumes (e.g. pumping configurations, plumbing design, mixer volumes, loading loop volume, tubing size).

2.3 Large Sample Volume Trace Enrichment

When purifying trace components from complex mixtures, it is imperative that the total sample be loaded if the optimum benefits of microcolumns are to be achieved. A typical application would be the repurification of a sample recovered from a conventional HPLC column, typically in volumes of several milliliters, on to a narrow-bore or microbore column at a suitable stage of a multidimensional purification protocol. Proteins and peptides bind very strongly (i.e. exhibit large capacity factors) to interactive supports (e.g. RP, IEX, HI or affinity matrices) below critical secondary solvent compositions (Figure 3). Under these conditions, trace enrichment of large sample volumes directly on to micropreparative columns is possible before recovering retained proteins or peptides in small volumes at high concentration by gradient or step elution.\(^{21}\) An important practical point is to ensure that the sample is in a buffer that will allow trace enrichment. Samples may require dilution to reduce the salt or organic solvent concentration used for elution at the previous chromatographic step. Samples are typically loaded at high flow rate (see the discussion on column back-pressures below) by means of a large-volume injection loop (up to 2 mL), often using multiple injections, a Superloop (up to 10 mL) (Amersham Pharmacia Biotech) or by direct loading via the primary or auxiliary pump. Large-volume injection loops should be switched out of the main flow path following sample loading to minimize the system volume between the pumps and the column, which would otherwise result in unacceptably long delays in gradient delivery. We have frequently loaded samples in volumes of up to 100 mL on to 1-mm i.d. RP columns and recovered the retained proteins in peak volumes of <100 µL (>1000-fold concentration).

2.4 Column Loading Capacity

Short narrow-bore, microbore or capillary columns must have adequate sample capacity to be a viable proposition for the micropreparative HPLC of proteins and peptides. We have shown that even short 30 × 2.1-mm i.d. RP columns [7-µm particle size, 300-Å pore size (1Å = 10\(^{-10}\)m)] have a capacity of over 4 mg of protein.\(^{21}\) However, at such loadings the column was obviously grossly overloaded, as evidenced by the recovery volume after stepwise elution (1.4 mL). An investigation of protein load versus peak volume showed that optimum efficiency could be maintained for individual protein loads up to 10 µg when using a 100 × 1-mm i.d. column. Comparison of varying column lengths (30 and 100 mm) showed that the optimum load was independent of length until the critical loading was exceeded, when the shorter column overloaded more rapidly with increasing sample (Figure 4).\(^{22}\) However, even when operating under overload conditions there are still significant advantages to be gained in terms of the sample recovery volume when using columns of reduced inner diameter. With complex mixtures, we
Figure 2 Separation of low-level protein standards by micropreparative reversed-phase high-performance liquid chromatography (RPHPLC). Protein standards were separated on a Brownlee RP 300 narrow-bore "guard column" (30 × 2.1-mm i.d.) using a linear 1% min⁻¹ gradient between 0.9% (w/v) NaCl (pH 2.1) and CH₃CN as indicated (dashed line). The flow rate was 100µLmin⁻¹ and the column temperature was 45°C. Detection was by absorbance measurement at 210 nm. The standards were ribonuclease A (RNase, 92 ng), murine epidermal growth factor (mEGF, 25 ng), cytochrome c (cyt c, 134 ng), lysozyme (lys, 80 ng), bovine serum albumin (BSA, 140 ng), bovine α-lactalbumin (α-lact, 94 ng) and myoglobin (myo, 79 ng). Simpson, 'Application of Short Microbore HPLC Columns for the Preparation of Samples for Protein Microsequencing', 187–195, Copyright (1985), with permission from Harcourt Brace and Company.)

Figure 3 Relationship between capacity factor ($k'$) and organic solvent concentration for the separation of proteins and peptides by RPHPLC. Proteins and peptides were chromatographed on a Brownlee RP 300 column (30 × 2.1-mm i.d.) at 25°C and a flow rate of 100µLmin⁻¹. The mobile phase was 0.15% (v/v) TFA mixed with CH₃CN at the concentrations shown. have frequently applied total protein loads of >1 mg on to 30 × 2.1-mm i.d. columns and recovered purified minor components of interest in the small peak volumes associated with such columns.

For capillary columns, it has been shown that similar criteria apply. Detection of proteins and peptides at the low-picogram level has been reported with resolution equivalent to that observed on larger bore columns. The optimum length appeared to be 20 cm.²³²³

2.5 Column Length

An important practical consideration with the use of columns of reduced inner diameter is the increased operational back-pressures associated with these columns, particularly if large sample volumes are to be loaded at high flow rates to minimize the total run time, since most chromatographic systems have operating pressure limits of 6000–10 000 psi. Back-pressures are further exacerbated when using either small particle size or nonporous supports, which have been shown to
function of the gradient profile, with only a narrow time window during which the true chromatographic process is operative. Thus, effective micropreparative protein and peptide separations can be achieved on columns (30 × 2.1-mm i.d.) that were originally designed as guard columns for use before 4.6-mm i.d. analytical columns and which only have a relatively low plate count. Such guard columns offer significant advantages in terms of cost, and can be virtually regarded as disposable when working with potent biologically active molecules where cross-contamination between samples can be disastrous.

2.6 Micropreparative Size-exclusion Chromatography

Different criteria apply when considering the dimensions of micropreparative columns for use with noninteractive size-exclusion supports. Efficiency (plate count) is of the utmost importance with such columns, and column length must therefore be maintained. In addition, samples cannot be trace enriched on to these columns and injection volumes become limiting [ideally the sample volume should be less than 2% of the column bed volume]. Because of these sample volume limitations, micropreparative size-exclusion columns are best used in the middle of multidimensional protocols following the use of interactive supports from which recovery of samples prior to bioassay or chemical or enzymatic manipulation.

2.7 Sample Recovery

Recovery is of primary importance in any purification technique. The use of short microcolumns has been shown to result in increased sample recovery compared with wider-bore columns. This is presumably due to the greatly reduced surface area of the packing exposed to the sample, with a corresponding reduction in the number of available sites for irreversible nonspecific adsorption.

Losses during chromatographic procedures can be due to both on-column losses and losses occurring during associated nonchromatographic sample manipulations (e.g., sample dilution, pH adjustment, storage, chemical manipulation). We have found that the use of an injection
Figure 5 Relationship between overall recovery and repetitive yield in multidimensional chromatography.

Syringe as a vehicle for performing sample dilution prior to reinjection and the use of low levels of nonionic detergent in the diluent (e.g., 0.02% Tween 20) help to reduce losses during sample manipulation.6,16,19 If the overall total system recovery can be kept high throughout the procedure, it is possible to take a sample through a number of successive chromatographic steps (multidimensional purification) and still have sufficient purified material available for structural and/or biological analysis. If the total recovery for each stage is >90%, a purification strategy of more than six sequential steps is possible with an overall recovery of >50% (Figure 5). Moritz et al. were able to demonstrate a repetitive total system recovery of 97% for five sequential micromanipulations of lysozyme (50 ng) on a 0.32-mm i.d. capillary column.34

2.8 Multidimensional Purification

The sequential use of microcolumns of varying selectivity, assuming they have good recovery characteristics, allows very high purification factors to be achieved. Indeed, it can be calculated (Table 1) that purification factors far in excess of those achieved by two-dimensional (2D) polyacrylamide gel electrophoresis (PAGE), which is generally accepted as being a high-resolution technique for the separation of complex mixtures of proteins and peptides, can be achieved using multidimensional purification protocols, with the added advantage that the purified sample is in a form directly compatible with downstream analysis. By careful consideration of the order in which columns are used in a multidimensional purification scheme, the need to manipulate the sample between stages can be minimized, thereby further improving overall recoveries. For example, samples recovered in small volumes from micropreparative IEX or HI columns can be taken directly on to size exclusion and then, being in aqueous solvents, can be loaded directly on to RP columns. We have used such an approach for the purification to homogeneity of murine EGF from salivary glands,35 a GTPase-activating protein from bovine brain36 and the membrane-associated A33 antigen from a colonic carcinoma cell line.37 Opitreck et al.38,39 have described automated 2D narrow-bore and capillary HPLC systems, using the orthogonal chromatographic modes of size exclusion and RP or cation exchange and RP, to separate complex protein mixtures.

3 INSTRUMENTATION

3.1 Narrow-bore and Microbore High-performance Liquid Chromatography

Suitable instrumentation for micropreparative HPLC requires (a) precise, pulseless pumping at low flow rates, (b) the ability to generate accurately and reproducibly gradients at low flow rates, (c) minimum dead volumes throughout the instrument and, for true micropreparative applications, (d) reliable and accurate recovery of small-volume fractions. These key requirements have been reviewed.40–43 A prototype liquid-delivery system in which thermal expansion is used to reproducibly deliver pulse-free flow at flow rates down to 10 nL min⁻¹ has also been described.44

Most conventional HPLC systems using high-pressure mixing can be readily modified for use with narrow-bore or microbore columns.21,43 In such cases, recovery will usually be effected by manual trapping, allowance being made for the dead volume between the detector flow cell and the collection port, which is significant when operating at low flow rates (<200 µL min⁻¹). Manual trapping usually involves holding the tip of the collection device either against the side of the collection tube (we usually use 0.5- or 1.5-mL Eppendorf tubes which have particularly good recovery and low-level background contamination properties) or under the liquid meniscus to prevent droplet formation. The drop size (typically around 10 µL) becomes extremely significant in terms of both resolution and overall recovery when dealing

*Peak capacity is defined as the number of peaks that could theoretically be resolved in a typical chromatographic run.
with peak volumes of 20–100 µL. Systems using prepump low-pressure mixing devices are generally not suitable for gradient elution at very low flow rates because of excessive instrumental volumes between the point of generation of the gradient and the head of the column, often of the order of several milliliters.

Relatively few HPLC systems have been designed specifically for micropreparative operation in terms of the requirements for both the chromatographic separation and microfraction collection. As an alternative to direct automatic collection of fractions into tubes or microtiter plates, the use of moving blotting membranes has also been described.\(^{45,46}\) Commercially available micropreparative instruments include the Amershams Pharmaceuticals SMART system (http://www.apbiotech.com), which has a built in microfraction collector,\(^{35,47}\) and the LC Packings instrument with the PROBOT fraction collector (http://www.lcpackings.nl),\(^{48}\) which can collect fractions on to a number of different substrates [matrix-assisted laser desorption/ionization time-of-flight (MALDI/TOF) targets, poly(vinylidene fluoride) (PVDF) membranes, 96-well microtiter plates].

One instrumental component which deserves further comment is the detector flow cell. The requirement for specially designed low-volume flow cells for narrow-bore and microbore chromatography is often overstated. Kirkland et al. have shown that combined postcolumn and detector flow-cell volumes up to 10% of the peak volume are allowable.\(^{49}\) In practice, we have found that detector flow-cell volumes of 4.6 µL are compatible with peak volumes of >50 µL. Flow-cell design, per se, is important, however, since poorly designed flow cells can cause turbulence or peak hold-up, and hence poor sample clearance and peak mixing. In addition, small-volume flow cells with reduced optical pathlengths have proportionally reduced sensitivity.

### 3.2 Capillary High-performance Liquid Chromatography

The recovery of protein and peptide samples in small (microliter) volumes that can be readily manipulated off-line for use in “downstream” high-sensitivity analysis is readily achieved with the use of 1-mm i.d. columns, where peak volumes of 20–50 µL are routine (volumes much less than 10 µL are not really desirable for manual off-line manipulations since postcolumn sample handling becomes difficult and even small volume losses are significant). However, the use of on-line MS for the high-sensitivity analysis of low (femtomole) levels of high-molecular-weight proteins,\(^{50}\) in which chromatographic techniques are the optimum method of introducing samples into the instrument,\(^{50–52}\) has stimulated the development of capillary HPLC techniques.\(^{23,34,53}\) As indicated above, the increases in performance observed with microbore columns are equally applicable to capillary systems, with concomitant reductions in peak volume and increases in sample concentration and hence sensitivity of detection.\(^{23,34,53}\)

Gradients need to be developed and supplied at flow rates of 10 µL min\(^{-1}\) or less with capillary columns (Figure 6). This is usually achieved by the use of stream-splitting techniques, in which gradients are generated at higher flow rates (e.g. 50 µL min\(^{-1}\)) but only 1–5% of the resulting gradient is passed through the column, the remainder of the solvent being diverted to waste.

The small peak volumes (low-microliter volumes or less) achievable with capillary HPLC of proteins and peptides means that on-column detection\(^{54}\) or specially designed low-volume flow cells [e.g. axial-beam longitudinal alignment (Z-cell), which yields longer pathlengths\(^{23,34,53,55}\)] are required. Commercially available instruments include the Ultimate Integrated Capillary HPLC system from LC Packings (http://www.lcpackings.nl), the Micro Pro modular system from Eldex (http://www.eldex.com), the Micro-Tech MicroLC (http://www.mtsscientific.com) and the PE-ABI 173A Microblotter cLC system (http://www.perkinelmer.com).\(^{56}\) The Ultimate system is capable of running at flow rates from 50 nL min\(^{-1}\) to 200 µL min\(^{-1}\).

### 3.3 Columns

Short (<10-cm) narrow-bore and microbore columns are now commercially available from a wide range of manufacturers, although they may be readily packed “in-house” using conventional slurry packing techniques.\(^{21}\) A range of packed capillary columns are currently available from LC Packings. However, the packing of
capillary columns in-house is also not difficult. Detailed instructions are given in the publications by Tong et al.,57 Huber et al.,58 and Kennedy and Jorgenson.59 It has been noted60 that capillary columns can be used for extended periods (up to 18 months) since they can be readily regenerated by trimming the top of the column to remove debris.

4 MICRO LIQUID CHROMATOGRAPHY VERSUS CAPILLARY ELECTROPHORESIS

The relative merits of micro liquid chromatography (LC) and capillary electrophoresis (CE) have been the topic of much discussion. CE is undoubtedly a rapid ultrasensitive analytical technique, exhibiting high separation efficiencies under relatively mild operating conditions (in terms of biological stability), with detection levels at the single molecule level for suitably labeled proteins using laser-induced fluorescence detection.61–63 However, with on-line ultraviolet (UV) absorbance because of the small detection cell volume and short optical pathlength, detection limits are in the micromolar range.64 A further significant limitation is the very small sample volumes (low-nanoliter level) that can be applied directly to CE. Whilst the development of on-line concentration devices has helped alleviate this problem,65–68 large sample loadings will probably not be possible owing to significant heat generation under the operating conditions used, which leads to a deterioration in performance. However, Figyes et al.68 have successfully used a 5-µm, 300-Å C18 packing as a solid-phase extraction device coupled to CE and electrospray ionization tandem mass spectrometry (ESIMS/MS) to identify low-nanogram quantities of yeast proteins previously separated by 2D electrophoresis. The volume loaded on to the extraction device was 15 µL.

By contrast, as we have described above, micro LC is compatible with the loading of large-volume dilute samples by trace enrichment, a necessity when purifying trace components. Thus, for many micropreparative applications the use of micro LC would appear to be the method of choice.

Jorgenson et al.69–71 have coupled the concentration potential of micro LC with the resolving power of CE in a multidimensional approach. Micropreparative size-exclusion chromatography (SEC)/CE and RPHPLC/CE were presented. Such systems may be even more applicable if capillary chromatography is used in the first dimension, where it would be possible to recover proteins and peptides in nanoliter volumes if using, for example, 50-µm columns.

5 CAPILLARY ELECTROCHROMATOGRAPHY

Capillary electrophromatography (CEC) is a hybrid between CE and HPLC, coupling the very high efficiency of CE with the high selectivity of HPLC. In the simplest (isocratic) form an apparatus identical with that in CE is used, solvent flow being generated by electroendosmotic flow at high voltage (typically 10–30 kV). Under these conditions, and using low buffer concentrations in the mobile phase (2–5 mM) to avoid Joule heating effects, a virtually linear relationship exists between solvent velocity and applied voltage. CEC can be performed in both open-tubular columns and capillaries packed with conventional supports.72,73 Neutral species are separated by a partition-based mechanism whereas the separation of charged species is based on both electrophoresis and partition. The velocity profile in electrochromatography approaches perfect plug flow (contrasting with parabolic flow observed in pressure-driven systems), resulting in very high chromatographic efficiencies limited only by axial diffusion.74 Because flow is generated electrically rather than by pressure, small particle diameter supports can be used, further enhancing the separation efficiency.75

Initially, CEC tended to be performed under isocratic conditions. However, modifications of the instrumentation to allow gradient elution have recently been described,68,76–78 enabling large samples to be trace enriched on to interactive supports and the full potential of such systems for the separation of proteins and peptides to be achieved. CEC has recently been coupled to ion trap/reflectron time-of-flight MS for the analysis of protein digests.79,80

6 APPLICATIONS OF MICROPREPARATIVE HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

Micropreparative HPLC is suited to a wide range of scientific disciplines where the recovery of trace components present in bulk biological samples is required prior to sensitive and specific downstream analysis (Figure 7). Although this article relates specifically to applications related to protein and peptide purification, the use of micropreparative HPLC is equally applicable to other classes of chemical compounds (e.g. steroids, pesticides, oligonucleotides), provided that sensitive and specific analytical methods are available for subsequent analysis.

For protein and peptide applications, the concentration of samples recovered from micropreparative HPLC
**MINIATURIZATION OF HPLC IN PEPTIDE AND PROTEIN ANALYSIS**

**Figure 7** Applications of micropreparative HPLC in protein and peptide research.

columns is such that a number of complementary downstream analytical techniques can be used (Figure 7). Indeed, even if only nanogram quantities of purified material are available, the recovered sample can often still be subjected to a number of different assays (e.g. bioassay, biosensor analysis, MS, immunochemical assays, sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE), and N-terminal sequence analysis).

### 6.1 Microsequence Analysis

Historically, the most significant use of micropreparative HPLC has been in the preparation of low-level samples for amino acid sequence analysis. Indeed, it was this application that initially led us\(^{16,19,21,22}\) and others\(^{20}\) to develop the use of microbore HPLC methodologies for the purification of proteins and peptides. These techniques have been used extensively in the isolation and characterization of a number of important biological molecules, including the hematopoietic growth factors and other members of the cytokine family.\(^{81–84}\) Typically, such purifications have involved multiple chromatographic stages utilizing several column packing materials with alternative different selectivity to achieve high purification factors as described above.

### 6.2 The Use of Micropreparative Ion-exchange Columns to Generate Samples for Microsequence Analysis

The use of narrow-bore and microbore RPHPLC columns to purify proteins and peptides has been generally accepted by most laboratories involved in microsequence analysis, and has resulted in numerous scientific publications which make use of this technique.\(^{18,19,30,85–88}\) However, RPHPLC is not a panacea, poor recoveries in particular being frequently observed for high-molecular-weight hydrophobic proteins. The use of micropreparative columns with different selectivities immediately prior to microsequence analysis would therefore greatly extend the general applicability of these microtechniques, provided that such columns could (a) resolve complex mixtures of peptides and proteins, (b) recover purified proteins in small peak volumes with high yield and (c) use mobile phases compatible with subsequent Edman chemistry, enabling samples to be loaded directly on to the sequencer following the final chromatographic purification.

We have shown that micropreparative IEX columns can be used in multidimensional chromatographic strategies for the purification of trace components in bulk biological samples.\(^{35,36}\) By careful selection of appropriate solvent systems the small eluent volumes obtained can be loaded directly on to the gas-phase sequencer and the N-terminal sequence obtained. In particular, the use of an aqueous sodium chloride gradient (20 mM–1 M, pH 6.5, i.e. a buffer-free system) was found to be compatible with subsequent microsequence analysis\(^{35,36}\) since sodium chloride does not interfere with the Edman chemistry. Indeed, sodium chloride appears to change the partitioning of the anilinothiazoline (ATZ) amino acids between the polybrene film used for immobilization on to the glass-fiber sample
disk of the sequencer and the extraction solvent (1-chlorobutane), leading to increased recovery of charged amino acids.\(^{89}\)

Recent developments in sequencer technology have also facilitated the analysis of buffer-containing samples. For example, the Hewlett-Packard G1005A protein sequencer\(^{90}\) uses a novel biphasic two-stage hydrophobic and hydrophilic reaction cartridge which permits processing, concentration and cleanup of samples directly on the sequencer cartridge. Large volumes (up to 5 mL) can be processed in a single application. Using the hydrophobic support, inorganic salts and buffers present in the purified fractions can be washed out using aqueous washes that can be either mildly basic or acidic. PE-ABI also offers a sample preparation cartridge (ProSorb) which will accommodate up to 400-µL samples and which is compatible with a wide variety of buffers and reagents (http://perkin-elmer.com).

Although microsequence analysis continues to be an important tool in the modern protein structure–function laboratory, recent advances in MS (see below) have demonstrated the use of gel electrophoresis, narrow-bore or capillary RPHPLC and MS to be a very powerful combination for the rapid characterization of proteins and peptides.\(^{91–94}\) Indeed, these technologies, coupled with sophisticated database analysis,\(^{95}\) form the basis of modern proteomics,\(^{96}\) the determination of the total protein complement of an individual genome.

### 6.3 Synergy of Micro Liquid Chromatography with Mass Spectrometry

MS has become an important technique for the analysis of biomolecules. In particular, MALDI/TOF\(^{97,98}\) and electrospray ionization mass spectrometry (ESIMS),\(^{99}\) which are both capable of accurately determining the molecular weight of proteins of over 100,000 Da with low-picomole to femtomole sensitivity,\(^{50}\) have had a major impact on protein and peptide analysis. In practice, these two techniques are very different. MALDI/TOF generates predominately singly protonated ions that can be analyzed using a time-of-flight mass detector. Electrospray ionization (ESI), by contrast, generates a series of multiply protonated ion species, many of which fall in the mass/charge range 500–4000 Da, which is compatible with modern quadrupole instruments. Additionally, structural analysis by tandem mass spectrometry (MS/MS) of ESI-generated peptide ions can be achieved.\(^{185}\) Fundamental to both of these techniques is the ability to generate the sample in a suitable form for direct analysis. Microchromatography systems appear ideal for this purpose.\(^{23,34,50–52}\)

#### 6.3.1 Matrix-assisted Laser Desorption/Ionization Time-of-Flight

MALDI/TOF is an “off-line” technique, in which the sample is purified and recovered prior to analysis. The sample is then mixed with a UV-absorbing matrix [e.g. sinapinic acid\(^{100}\) a-cyano-4-hydroxycinnamic acid\(^{51}\)] and applied to the inert target probe of the mass spectrometer. The matrix absorbs energy from a pulsed UV laser, causing ionization of the sample, whose mass is then determined by time-of-flight MS. MALDI/TOF is suitable for the analysis of mixtures of proteins or peptides, and it is relatively insensitive to salts [a key feature of the technique first demonstrated by Beavis and Chait\(^{100}\)], although improved sample application methods have been described\(^{101}\) that enable salts and impurities to be washed off the prepared samples, improving both resolution and sensitivity. MALDI/TOF has small sample volume requirements (typically 0.5–1 µL of sample is mixed with an equal volume of matrix solution) and high (femtomole) sensitivity, making the technique ideally suited to the direct analysis of samples purified by micropreparative HPLC.\(^{102}\) The proven compatibility of these two techniques has resulted in the development of low-volume fraction collectors designed specifically for direct application to MALDI/TOF targets (see section 3). A method has been described in which proteins and peptides are further trace enriched during vacuum concentration on to RP packing material if even higher sensitivity is required.\(^{103}\)

MALDI/TOF has also been used for direct protein sequence analysis.\(^{104}\) First, a concatenated series of peptide fragments, differing from each other by a single residue, is generated in a controlled fashion by rapid stepwise degradation in the presence of a chain-terminating agent (ladder-generating chemistry), or by using the enzyme carboxypeptidase Y (specifically for generating a C-terminal sequence). The complete ladder generated in this manner can be analyzed by MALDI/TOF. The mass differences correspond to the amino acid residue removed at each step, and hence define the sequence of amino acids in the original chain. Subpicomole amounts of protein can be rapidly analyzed with a mass accuracy of up to 1 part in 10,000. However, as with other methods of sequence analysis, a homogeneous sample facilitates analysis.

#### 6.3.2 Electrospray Ionization Mass Spectrometry

ESIMS is frequently used as an “on-line” technique in which an aqueous solution is introduced into the instrument through a needle held at high voltage. Ionization is caused by desolvation of droplets created under atmospheric pressure in an electrospray process between the needle and a grounded nozzle. Separation techniques
such as microbore or capillary HPLC, CE or more recently CEC are therefore the methods of choice for sample introduction. Unfortunately, CE is sample limited (only low-nanoliter volumes are compatible), although on-capillary sample concentration methods have partially alleviated this problem and both mass analysis and sequence determination at the low- or even sub-femtomole level have been reported. Additionally, ESIMS compatibility with the electrolytes used for capillary zone electrophoresis (CZE) is essential. The use of a suitable sheath liquid can minimize buffer-related effects, but the dilution effect of the sheath liquid can reduce the sensitivity of the analysis.

By comparison, as we have illustrated above, trace enrichment on to microscale RPHPLC columns permits the whole sample to be applied, irrespective of volume, provided that concentrations of organic solvent which would prevent interaction with the support are not exceeded (see Figure 3). Narrow-bore, microbore and capillary systems are now used widely for the introduction of proteins and peptides into the mass spectrometer. The column eluate can also be split prior to the mass spectrometer, allowing part of the separated sample to be recovered for additional analyses (e.g. microsequence analysis).

The success of this technique has facilitated the low-level analysis of peptide maps from novel proteins and is now the method of choice for the assignment of disulfide bonds in native and recombinant proteins, identification of post-translational and other modifications of proteins and peptides, identification of peptides bound to major histocompatibility complex (MHC) molecules and the identification of naturally occurring protein variants. Narrow-bore and capillary chromatography have also been used for the analysis of UV-cross-linked protein–nucleic acid complexes, where the identity of a tryptic peptide was confirmed by on-line capillary RPHPLC/ESIMS/MS, using 25 pmol of the peptide digest.

### 6.4 Chromatographic Recovery of Proteins from Polyacrylamide Gels

PAGE is now a widely used technique for the separation of complex mixtures of proteins and peptides. Up to 10 000 individual protein species have been separated in a single run using high-resolution 2D techniques. The general applicability of PAGE is further enhanced when coupled to ancillary protein recovery techniques (e.g. passive elution, electroelution, electroblotting). Because gel electrophoresis is compatible with the separation of low levels of protein, micropreparative HPLC techniques have often proved beneficial in subsequent sample manipulation. A number of alternative protocols have been proposed, including “inverse gradients” for the efficient recovery of pure proteins from gel electrophoresis, free of high concentrations of sodium dodecyl sulfate- and polyacrylamide gel-related artefacts and a micropreparative technique in which protein spots from 2D gels were excised, minced and placed directly in a precolumn connected in series with a short RPHPLC cartridge (20 x 2 mm i.d.). In an extension of this method, Tetaz et al. performed “in-gel” digestion in situ in the precolumn and then recovered the generated peptides.

Methods utilizing micropreparative HPLC for the purification of peptide fragments generated using a gel-based approach have also been described. Aebersold et al. described a generally applicable method in which proteins were electroblotted from 2D gels onto nitrocellulose. Spots were then excised and the samples eluted with 100% TFA. The volatile TFA was then evaporated and the eluted protein digested either chemically or enzymatically followed by separation of the resulting peptides by narrow-bore RPHPLC. However, poor recoveries (<10%) have been observed following electroblotting and electroelution, and therefore methods have been developed for in-gel digestion followed by passive elution and chromatographic separation of the generated peptides. The method of Hellman and Renlund has been shown to be compatible with low-level samples separated on precast minigels (Phastgels, Amersham Pharmacia Biotech).

Although 2D electrophoresis is now widely used for the separation of complex protein mixtures from whole cell lysates for proteome studies, one of the major limitations is that trace components are frequently not detected, often being overshadowed by more abundant proteins. This can be avoided by the use of preliminary fractionation, either chromatographically using preparative columns to facilitate gel loading, using preparative electrophoretic techniques such as free-flow isoelectric focusing, by subcellular fractionation or by a combination of these techniques.

### 6.5 Database Searching Strategies

The combination of 2D electrophoretic separations, micro LC and MS is complemented by another emerging technology, peptide mass fingerprinting, in which observed masses are compared with computer-generated peptide molecular weights derived from site-specific proteolytic cleavage of proteins whose sequences are already in the continually expanding DNA and protein databases. For this technology, MALDI/TOF/MS or capillary HPLC/ESIMS have been used to generate the required peptide mass information from chemical or
enzymatic digests of the unknown protein of interest. It has been suggested that as few as 5–7 peptides are required for unambiguous matching with a particular protein present in the databases. This technique is particularly effective when studying organisms where the complete nucleotide sequence of the genome is available.

A second method involves the use of data generated by MS/MS. This generates highly specific information in the fragmentation pattern as well as sequence information and is a general solution when solving data from incompletely resolved protein mixtures. A database (SEQUENT) has been developed to use the fragmentation pattern to identify the amino acid sequence represented by a tandem mass spectrum.

6.6 Synergies Between Micropreparative High-performance Liquid Chromatography and Instrumental Biosensors

The application of molecular genetics and recombinant DNA technology in biomedical research and the development of the Human Genome project have led to the isolation of many genes encoding proteins whose biological function and possible binding partners remain unknown. Furthermore, an exponential number of new compounds with potential therapeutic effects have been produced by combinatorial techniques or obtained from natural product libraries. New strategies and complementary technologies including novel affinity methods are therefore required for the screening and functional characterization of these proteins and small molecules. In response to this need, interdisciplinary studies in chemistry, electronics and biology have led to the research and development of a number of novel interfaces for biomolecular electronic devices and sensors. Reflecting this impetus in research and development, a number of instrumental biosensors, suitable for a wide range of research applications, are emerging and are rapidly becoming a major tool in the field of biomedical research, in particular in the area of biomolecular interaction. The optical biosensors [BIAcore® range from BIAcore, Uppsala, Sweden (http://www.biacore.com) and IAsys systems from Affinity Sensors, Cambridge, UK (http://www.affinity-sensors.com)] are successful illustrations of this new generation of instrumental biosensors.

These evanescent wave sensors do not require the use of labeled reagents for detection since signals are generated through a change in mass loading when an interaction occurs. The BIAcore® uses the technique of surface plasmon resonance (see also Surface Plasmon Resonance Spectroscopy in Peptide and Protein Analysis) while IAsys uses a waveguide technique called a prism coupler or resonant mirror. These instruments continuously monitor the resonance angle and thus can detect changes in the refractive index caused by changes in sensor surface mass. The BIAcore® sensor surface consists of a glass slide coated with a thin (50 nm) gold film to which is attached, by an inert (alkanethiol) linker layer, a chemical matrix on to which one of the binding partners can be immobilized using well-defined chemistries. The IAsys sensor surface is the bottom of a microcuvette possessing its own integrated optics; a choice of derivatized surfaces is available.

Specific ligands (proteins, peptides, carbohydrates, lipids, DNA) can be immobilized on the sensor surface at low concentration using various strategies: covalent attachment through amine, thiol or aldehyde chemistry, capture via biotin–avidin interaction or specific tags or immobilization using HI chemistries. Real-time binding studies can be performed by sequentially flowing reagents of interest over the biospecific sensor surface. Concentration and kinetic data can be obtained by analyzing the binding curves generated. Recovery of specifically bound material for downstream analysis (e.g. MS, PAGE) is possible with these instruments. In particular, the microcuvette of the IAsys sensor is very suitable for this purpose owing to the availability of a high-capacity sensor surface (CMD select cuvette, 10–20-µg range), the potential for long contact times and the confined environment, which facilitates recovery postdesorption in small eluate volumes.

6.6.1 Sample Compatibility Between Micropreparative High-performance Liquid Chromatography and Biosensor Analysis

Optical biosensors have been shown to be capable of detecting biomolecular interactions at low nanogram per milliliter concentrations, corresponding to levels of ligand often observed in biological samples. However, absolute sensitivity for a particular interaction depends on several factors, including the relative masses of the interactants, immobilization level, association and dissociation rate constants for the interaction and injection volume. The autoinjection systems of these biosensors are capable of accurately injecting samples down to 1 µL. As we have described above, short micropreparative HPLC columns (1–2-mm i.d.) can detect low levels (nanograms to micrograms) of proteins or peptides with sample recovery in small volumes (20–100 µL) at high concentration. Therefore, the sensitivity and sample recovery volumes characteristic of micropreparative HPLC are complementary with the biosensor requirements, allowing the two instruments to be used in a “bidirectional
synergy": micropreparative HPLC can generate highly purified reagents in a form suitable for the biosensor, and the biosensor can provide specific information to aid the chromatographic process.(142) Indeed, the biosensor can be considered as a micropreparative affinity surface with on-line detection comparable to a chromatographic immunoaffinity system. Samples recovered from micropreparative columns can often be analyzed without further manipulation by taking samples from the micropreparative HPLC fraction collector directly to the autosampler racks of the biosensor, except following RPHPLC where volatile organic and acidic solvents are either buffer exchanged using micropreparative SEC or removed by lyophilization prior to sensor analysis. In a further example of the compatibility between chromatography and biosensor analysis, the column effluent of a Superose 75 size-exclusion column has been coupled directly to an optical biosensor; the elution of a human scFV against 2-phenyloxazol-5-one (OX) present in concentrated conditioned media was detected on-line using immobilized OX – BSA hapten on the sensor surface.

6.6.2 The Use of Micropreparative High-performance Liquid Chromatography to Generate Reagents for the Biosensor

Biosensor specificity depends critically on the homogeneity of immobilized material. Samples should be purified to homogeneity and characterized immediately prior to immobilization, since heterogeneity of immobilized material has been shown to cause complex kinetics.(144–146) It is also important to remove high-molecular-weight aggregates, which might display avidity effects complicating kinetic studies.(143) Micropreparative SEC or desalting columns are ideally suited for the buffer exchange of samples into immobilization or running buffers prior to analysis. This purification step minimizes buffer-related refractive index changes (evanescent wave optical detectors are exquisitely refractive index sensitive) which may hinder interpretation of binding data for weak or low-level interactions, and removes buffer components which might interfere with subsequent binding (e.g. inappropriate pH, high salt concentrations, amine-containing buffers which would poison the N-hydroxy succinimide/N-ethyl-N’-dimethylaminopropyl carbodiimide immobilization).

6.6.3 The Use of Biosensors to Monitor Chromatographic Purification

Having immobilized a specific reagent on the sensor surface, the biosensor can be used to screen a wide range of biological extracts (e.g. tissue and cell culture conditioned media, cell extracts, biological fluids, combinatorial libraries) for possible sources of interacting proteins. These samples can be screened automatically using the robotic autosamplers of automated instruments. This screening approach has been shown to be particularly useful in the search for unknown ligands of, for example, monoclonal antibodies raised against complex mixture of proteins(37) or orphan receptors identified by the polymerase chain reaction or database-searching strategies.(129,141) In such cases, the sensor can then be used as a specific detector for monitoring fractions during chromatographic purification of the ligand of interest,(142) for detailed structure–function studies or may even be used directly as a micropreparative affinity surface.(147–150) Since the instrument can measure concentration, recovery and specific activity data can be readily calculated by reference to an appropriate calibration graph. In the case of novel proteins, this can be calculated retrospectively.(37)

Obviously, the complexity of a specific purification protocol will depend largely on the relative abundance of the ligand and the nature of the contaminant proteins present. In the identification and purification of the ligand for the orphan human HPH-like receptor tyrosine kinase (HEK) from human placental conditioned medium,(151) where the specific biosensor response observed during the initial screening was only 10 RU (close to the detection limit of the system), seven chromatographic steps were necessary to purify the ligand to homogeneity for amino acid sequence analysis, including micropreparative anion exchange (MonoQ PC1.6/5) followed by micropreparative RPHPLC (Brownlee RP 300, 50 × 1-mm i.d.). Using this protocol, 1.5 µg of protein was recovered with a purification factor of 1.8 × 10⁶ and an overall yield of 9%.

6.7 Liquid Chromatography/Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy used in conjunction with HPLC and MS has the potential to generate both chemical and structural information for the characterization of small molecules separated from complex mixtures. LC/NMR analysis has been applied in the fields of polymer, synthetic combinatorial and clinical chemistries and also in pharmaceutical, natural product and environmental analysis. The current sensitivity obtained in conventional HPLC/NMR in a continuous-flow mode is in the low-micrograms range.(152) However, stop-flow analysis, where the flow is stopped after the peak has entered the detector cell prior to NMR analysis, increases the sensitivity to the high-nanograms level. The volumes of NMR flow cells used in conventional HPLC/NMR are in the range 60–180 µL, which can lead to a loss
of chromatographic resolution. However, the introduction of a second dimension, the proton chemical shift, results in partial compensation of the chromatographic dispersion and allows the differentiation of co-eluting peaks. The current direction in research and development is towards the miniaturization of the coupled chromatographic separation NMR detection system [e.g. development of microcoil probe heads, interfacing with micro or capillary HPLC]. This miniaturization leads to a reduction in the use of solvents (making the use of fully deuterated solvents feasible) and therefore removes the need for solvent suppression, which leads to peak distortion.

The recovery of samples at high concentration from microbore and capillary HPLC is compatible with the use of microcoil detectors in NMR. These microcoils are suited for mass-limited applications (e.g. biological analysis, combinatorial libraries). It has been calculated that a 400-fold change in cell volume will lead to only a marginal reduction in signal-to-noise ratio. In practice, the use of a 31-nL microcoil actually gave a 10-fold enhancement in mass sensitivity compared with a 40-µL nanoprobe, allowing the acquisition of a detectable signal in 9 min compared with 15 h with the nanoprobe. The technical aspect of combining microcoil and capillary HPLC and the future direction of microcoil NMR have been reviewed by Olson et al.

7 FUTURE DIRECTIONS

The potential of Microsystems in the field of the separation sciences is now well established, in particular for the recovery of trace components in bulk biological systems. In the field of micro LC systems, further advances in instrumental design, particularly in the direct generation of gradients at submicroliter flow rates for capillary systems, is likely to facilitate operation.

The major benefits of such systems are realized by coupling them, either on- or off-line, with downstream sensitive and specific methods of detection. Current methods are compatible with femtomole levels of material for many applications, sufficient even for the analysis of single cell constituents in certain biological systems. However, the search for even more sensitive methods, aiming ultimately at single molecule detection, will continue to be a priority. To this end, it is worth noting that atomic force microscopy has recently been shown to be compatible with the characterization of ligand-binding forces in molecular repertoires at the single molecule level.

Another area that will almost certainly see further interesting developments in the near future is that of column packing materials and column technology. Affinity-based systems will almost certainly continue to gain prominence, often exploiting the exquisite selectivity obtainable with direct on-line analysis. Molecular imprinting, which creates selective recognition sites by polymerization of functional monomers in the presence of the imprint molecule, should play a role in this area. Particle size will continue to drop, or be replaced by monolithic stationary phases (where the packing is a continuous porous bed) or open-tubular columns in which the stationary phase is bonded to the column wall. These approaches are particularly amenable to CEC, where flow is not pressure generated.

However, perhaps the main limitation of existing micro LC systems is in the potential for high-throughput screening, since even with column-switching devices the number of concurrent analyses which can be performed is limited. An automated system incorporating an affinity extraction column and two RP columns coupled to a mass spectrometer has been described for the characterization of combinatorial chemical libraries of small drug compounds. However, this was only illustrated using a small 20-component library, a far cry from the current state of the art. The use of microfabricated systems may increase throughput.

7.1 Microfabrication Technology for Miniaturized Separation Systems

Microfabrication technology is suitable for both automation and integration, and is ideally suited for massively parallel high-throughput tasks. Additionally, the use of such systems could further reduce both sample losses and the introduction of contaminating proteins from the environment (e.g. keratins), a major problem for the micromanipulation of samples at the sub-nanogram level. These devices are usually fabricated from silicon, glass or plastic, often using techniques emanating from the microelectronics industry (e.g. photolithography, chemical etching, thermal bonding). An ultimate goal of this research is the development of fully integrated miniaturized analytical systems: a “lab-on-a-chip”. Chips with heaters, valves, pumps, microfluidics and sensitive detection systems have been described, in addition to integrated systems incorporating several techniques.

Reflecting these developments, a number of instruments have already been described for LC, CE, and CEC, particularly for direct coupling to MS.

Since the 1970s, high-performance liquid chromatography/mass spectrometry (HPLC/MS) has gone through many stages of development. The main technical challenge has been the coupling of liquid chromatography (LC) systems with mass spectrometers. Soft ionization techniques that have contributed to HPLC/MS for peptide and protein study include fast atom bombardment (FAB), matrix-assisted laser desorption/ionization (MALDI), and electrospray ionization (ESI). Among these techniques, FAB was developed first and used extensively in the 1980s; it lacked the sensitivity of the other two more recent techniques. MALDI and ESI are comparable in terms of sensitivity and the types of biomolecules that can be analyzed. However, MALDI has the slight advantage of being more tolerant to salts and able to analyze complex mixtures. On the other hand, the ability of ESI to interface mass spectrometry (MS) directly with LC makes it extremely useful for protein and peptide analysis. Another advantage that ESI offers is its ability to produce multiply charged protein ions, which allows the observation of large proteins with mass analyzers of limited mass range.

In this article, we discuss the experimental parameters that are important in HPLC/MS and the considerable progress made in ESI source design and capillary HPLC/MS.

In the study of natural and synthetic peptides, HPLC/MS has been used to separate, characterize, and sequence the peptides being investigated. In protein analysis, HPLC/MS is most useful in characterizing protein posttranslation modification such as glycosylation and phosphorylation. We discuss specific HPLC/MS methods for detecting glycopeptides and phosphopeptides during chromatographic separation by monitoring marker ions: Hex$^+$ (m/z 163), HexNAc$^+$ (m/z 204), NeuAc$^+$ (m/z 292), and HexHexNAc$^+$ (m/z 366) for glycopeptides.
and PO$_2^-$ (m/z 63) and PO$_3^-$ (m/z 79) for phosphopeptides. Another important application of HPLC/MS is in proteomic analysis. Here, the most significant development in the first decade of proteomics analysis has been the implementation of MS as the primary analytical technique to identify proteins separated by two-dimensional polyacrylamide gel electrophoresis (2-D/PAGE). Additionally, the need to identify gel-separated proteins has promoted various MS-based protein database search strategies. These include peptide mass mapping using proteolytic peptide masses for database search and using peptide fragmentation data obtained from tandem mass spectrometry (MS/MS) to search protein sequence databases. Finally, we examine the more recent advances in proteomics in integrating multidimensional LC–MS/MS and the analysis of large-scale proteomics datasets.

1 INTRODUCTION

HPLC/MS is one of the most powerful tools in peptide and protein analysis today. Complementary to HPLC/MS, capillary electrophoresis/mass spectrometry (CE/MS) is another highly efficient separation technique that can be coupled directly with MS using ESI, and the technique has proven to be very sensitive.$^1$ The popularity of HPLC/MS has resulted from the developments in both chromatography and MS.$^{2-5}$ The advances in soft ionization, in particular MALDI$^6$ and ESI,$^{7-9}$ have not only broadened the range of biomolecules that can be analyzed but also provided unprecedented sensitivity. Parallel to the development of MS, the utilization of capillary high-performance liquid chromatography (HPLC) column technology in conjunction with electrospray ionization mass spectrometry (ESIMS) has further extended the detection limits. HPLC/MS has been applied in many areas of peptide and protein study. For peptide analysis, this method has proved to be useful from the routine screening of synthetic peptide products to the study of naturally occurring peptides at the femtomole level. One of the major contributions HPLC/MS had made in protein analysis is in the characterization of protein posttranslational modifications. Notable examples are the analysis of phosphoproteins and glycoproteins, primarily by using the technique of monitoring diagnostic marker ions. As a result of genome projects in the 1990s, there is an increasing need to develop analytical tools for proteomics research. The combination of database search, multidimensional HPLC, and MS/MS has become an ideal format for large-scale high-throughput automatic identification of proteomics analysis.

2 INSTRUMENTATION OF HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY FOR PEPTIDE AND PROTEIN ANALYSIS

2.1 Early Development of High-performance Liquid Chromatography/Mass Spectrometry

The coupling of LC and MS combines the advantages of two powerful techniques of separation and detection. The resulting liquid chromatography/mass spectrometry (LC/MS) method provides one of the most popular analytical tools for peptide and protein study today. Since the 1970s, the development of the LC/MS has focused on resolving the fundamental problems of the coupling of the two techniques. The major technical issues that need to be addressed are the compatibility of the flow rate from the LC system to the vacuum system of the mass spectrometer, the compatibility of the mobile phase of the LC separation and the operation of MS, and the ionization of the analyte molecules.

In the 1980s, LC/MS systems that reached maturity and were made commercially available included moving-belt interface,$^{10}$ thermospray,$^{11,12}$ particle beam,$^{13}$ and continuous-flow FAB.$^{14}$ The moving belt was one of the first commercial LC/MS interfaces available in the 1970s. In a moving-belt interface, the flow from an LC column is deposited on a moving belt and the solvent is evaporated by heating. The analyte is desorbed from the belt and introduced into the mass spectrometer for mass analysis. The introduction of thermospray interface in 1983 by Vestal$^{15}$ was a major advancement in the development of LC/MS. Adding heat to the ionization source, thermospray is produced when column effluent passes through the capillary vaporizer, the liquid becomes partially vaporized by the heat, resulting in a supersonic jet of vapor with particles or droplets entrained. This technique was used for LC/MS studies on peptides and proteins.$^{15}$ In a particle beam LC/MS interface, the column effluent is nebulized, either pneumatically or by thermospray, into a desolvation chamber, which is connected to a momentum separator to transfer the analyte into an electron impact/chemical ionization (EI/CI) ion source for mass analysis. The continuous-flow FAB interface adapted for LC/MS uses FAB ionization$^{16}$ and an interface connects a small liquid flow of 5–15 µL min$^{-1}$ consisting of FAB matrix such as glycerol to the FAB target.$^{14}$ Ions are formed by bombarding the liquid film formed on the target with fast atoms or ions. Although these interfaces provide ways to perform LC/MS, the capability for protein and peptide applications is still limited owing to the difficulty of producing molecular ions directly from the liquid phase.
2.2 Electrospray Ionization

Mass spectrometric measurement of the \( m/z \) values of proteins and peptides requires ionization of these polar and charged molecules in the gas phase. A major breakthrough in biological MS has been the development of ESI for biomolecules.\(^{(7–9)} \) At present, the majority of LC/MS systems for peptide and protein analysis are based on this ionization technique. The ESI source had been investigated by Dole in the 1960s while attempting to produce charged macromolecules by electrospraying a solution of polystyrene. Experimentally, the electrospray is produced by applying an electrical potential of several kilovolts to a sample liquid flowing from a metal capillary.\(^{(17)} \) As effluent passes through the needle tip, electrical charge is deposited on the surface of the liquid emerging from the capillary, and Coulomb repulsion forces are produced, which break down the liquid into small charged droplets. The charged droplets shrink by solvent evaporation, and the charge migrates to the surface of the droplets. When the repulsive forces exceed the surface tension, the droplet disintegrates, producing analyte ions in the gas phase for mass analysis. Since electrospray (optionally) operates without heat, nonvolatile thermal labile and polar molecules can be ionized without degradation. Furthermore, ESI is uniquely suited for LC/MS because it can couple directly to HPLC effluent. The practical importance is that the ESI spectra of the peptide and protein ions display a characteristic multiple charged ion series \([M+nH]^+\), which give rise to a series of consecutive peaks of \( m/z \) \((M+n)/n\); molecular mass can be determined from any two consecutive peaks differing by one proton in the series. In general, the maximum number of protons attached to proteins or peptides correlates with the total number of basic residues (e.g. Arg, Lys, His), plus the N-terminal amino group. In practice, a distribution of many ions is seen, each differing by one charge from its neighbor and corresponding to a variable number of protons added to the protein. A protein of 10000 Da with 10 added protons will yield an \( m/z \) 1000 protein ion in ESI, \( m/z \) 1112 with 9 added protons, \( m/z \) 1251 with 8, and so on. As a result, measurement of \( m/z \) values of biomolecules with high mass can be made in the mass range \( m/z \) 500–2000, which allows common mass analyzers with limited mass range, such as a simple quadrupole instrument, to study large proteins.

2.3 Instrumentation for High-performance Liquid Chromatography/Mass Spectrometry

Built on the early research by Dole, Fenn et al. presented a practical implementation of the ESI for LC/MS in 1985.\(^{(18)} \) In their design (Figure 1), a sample solution passes through a 100-µm-i.d. stainless steel hypodermic needle at a flow rate of 5–20 µL min\(^{-1} \). The electrospray needle is held at ground potential and the cylindrical electrode is held at −3.5 kV (for positive-ion detection). The liquid droplets emerging from the tip of the electrospraying needle are dispersed by a countercurrent of heated nitrogen gas. The solvent that evaporates from the droplets is swept away by the bath gas, and the analyte ions enter the mass analyzer through a glass capillary. In a later design described by Chait et al.,\(^{(19)} \) the transport and desolvation of analyte ions are carried out with a heated stainless steel transfer capillary. Pneumatic nebulization, an ion-spray LC/MS interface that combines the ion evaporation principle suggested by Iribarne and Thomson, with ESI was demonstrated by Bruins et al. in 1987.\(^{(20–23)} \) In this design, the effluent from the liquid chromatograph is fed through a pneumatic nebulizer floating at several kilovolts relative to the sampling orifice (OR) of the ion source, liquid is dispersed into charged droplets in dry nitrogen gas at atmospheric pressure, and the nebulizing action is assisted by the coaxial high-velocity gas flow. The main advantage of the pneumatic-assisted ion-spray interface is its ability to handle higher flow rates of up to 200 µL min\(^{-1} \). In a coaxial electrospray interface designed for CE/MS, Smith et al. have developed a liquid sheath electrospray source.\(^{(24)} \) The electrospray needle of this interface consisted of three coaxial capillaries, with the two outer capillaries made of stainless steel and the inner capillary made of fused silica. The organic sheath liquid flow, usually consisting of pure methanol or acetonitrile, sometimes with a small amount of acetic acid, is introduced from the annular space of the outer capillaries. Various commercial LC/MS sources have been reported.\(^{(25,26)} \) Much of the progress made in the source...
design focuses on the central issue of optimizing the nebulization process in ESI. For example, a curtain gas that opposes the path of the droplets to sweep away larger undesolvated droplets has been incorporated into Perkin-Elmer SCIEX’s quadrupole instruments. In a different approach, increased vaporization was achieved by delivering heat into the nebulized plume. A heated electrospray source has been designed by Vestec, without the countercurrent or nitrogen curtain gas. In a design different from the conventional in-axial (relative to the sampling OR) electrospray source, the Hewlett-Packard/Bruker orthogonal electrospray instrument ESQUIRE-LC™ ion trap uses an electrospray ion source that is orthogonal to the sampling OR (Figure 2).\(^{(27)}\)

The desolvation, transport, and declustering of analyte ions are achieved by the combined use of heated nitrogen gas and a dielectric glass capillary sampling device. The orthogonal geometry offers the advantage of reducing the contamination of the sampling OR and enhances the signal-to-noise ratio by minimizing the sampling charged droplets. An orthogonal sampling adapter used in the Finnigan’s LCQ Deca™ ion trap electrospray instrument was reported to be very robust and capable of handling nonvolatile buffers. In a different approach, the electrospray source called a pepperpot was made by Micromass for their quadrupole instrument. This device and the modified cross-flow version allow sampling of the ions from the electrospray plume with desolvation and trapping of the nonvolatile materials. In the latest version of this device called Z-spray, analyte ions are extracted orthogonally into the mass analyzer sampling OR.\(^{(5)}\)

Almost all the major types of mass analyzers have been coupled to HPLC as detectors. In general, mass spectrometers are used to simply measure the intact molecular weight of peptides or proteins; in these cases, single-stage mass spectrometers (MS) are used.

To determine additional structural features of peptides and proteins, including amino acid sequence information, multistage mass analyzers capable of performing MS/MS are commonly used. These mass analyzers may differ in their designs and operational principles; the more widely used mass analyzers for LC/MS applications belong to the four basic types: ion trap, time of flight (TOF), quadrupole, and Fourier transform mass spectrometry (FT-MS). These mass analyzers can also be put together in tandem to combine the strength of individual analyzers. Notable examples are triple quadrupole (Q–Q–Q), hybrid quadrupole time of flight (Q–TOF), tandem time of flight (TOF–TOF), and linear ion-trap-FT/ICR (LIT-FT/ICR). Very recently, a new type of mass analyzer called orbitrap has emerged as one of the more powerful tools that has the characteristics of an FT/MS spectrometer but does not need a superconducting magnet.\(^{(9)}\) Compared to the previous generation of mass analyzers, these mass spectrometers offer improved mass accuracy, resolving power, sensitivity, and MS/MS capabilities to meet the evolving analytical demands.

MS/MS is an important tool in LC/MS experiments. The four most common MS/MS experiments are (i) product ion scanning, (ii) precursor ion scanning, (iii) neutral-loss scanning, and (iv) multiple ion monitoring. The selection of a specific type of MS/MS operation depends on the information desired. The product ion scan selects a precursor with the first stage of a mass analyzer, fragments it by collision-induced dissociation (CID), and scans the second-stage mass analyzer to obtain a product mass spectrum. Product ion scanning mode is frequently used for determining the peptide sequence. In precursor ion scan, a specific product ion is selected with the second mass analyzer, and the first mass analyzer scans over a specific mass range, selecting precursor ions of different \(m/z\) that fragment to yield the specific product ion. This mode is used to screen a class of compounds that fragment to a common substructure. In a neutral-loss scan, both mass analyzers scan with a constant difference in mass. The resulting neutral-loss spectrum produces product ions that arise from the loss of a neutral fragment from the precursor ion. Precursor ion scanning and neutral-loss scanning are often used in detecting posttranslational modifications such as phosphorylation and glycosylation, using specific marker ions produced in the fragmentation process. The multiple ion monitoring is commonly used for quantitative analysis, where a specific precursor–product ion pair is monitored for a particular molecule of interest. In addition to the conventional MS/MS techniques for proteins and peptides, mass spectrometric-based methods such as electron capture dissociation (ECD) and electron transfer dissociation (ETD) offer alternatives for peptide fragmentation; unlike CID, however, these techniques

**Figure 2** An orthogonal ESI source interface. Desolvation, transport, and declustering of analyte ions are optimized by using heated nitrogen drying gas and a glass capillary.\(^{(27)}\) (Reproduced by permission of Hewlett-Packard from Hewlett-Packard Technical Note MS/MS TN97-1.)
tend to fragment in a more evenly distributed manner along the peptide backbone, and they are useful in identifying posttranslational modifications.

### 2.4 Capillary High-performance Liquid Chromatography/Mass Spectrometry

The detection limits for peptides and proteins by MS have dropped significantly from approximately 1 nmol in the 1980s to the low picomole to the femtomole range in the 1990s. Parallel to this development, the trend of using smaller diameter columns become clear. The applications have moved from analytical columns (4.6 mm i.d.) to microbore (1 mm i.d.), and more recently to capillary columns (<0.5 mm i.d.). The basic chromatography theory predicts that reducing the column diameter will increase sensitivity in a relationship, which is inversely proportional to the square of the column diameter. This relationship is summarized in Table 1.

One of the main technical issues in HPLC and MS interfacing is what HPLC flow-rate ESI can accommodate. For effective nebulization, the optimum operation of ESI requires a stable spray of small charged droplets produced by low flow-rate conditions, typically of the order of 1–10 µL min\(^{-1}\). Although initially the interest in developing capillary columns was to improve separation efficiency, the decrease in flow rate with reduced column inner diameter is ideal for HPLC/MS. As shown in Table 1, the flow rate of a packed capillary is decreased to about 1–15 µL min\(^{-1}\). As the column inner diameter decreases, the injection volume and loading capacity also decrease, leading to improved detection limits (Table 1). In peptide and protein analysis, the characteristics of capillary columns match the ever-increasing demand for techniques to analyze the small amount of materials in a minute sample size (e.g. proteins isolated by 2-D/PAGE). Generally, for low-sensitivity analysis (>1 nmol), 4.6 or 2.1-mm-i.d. columns are sufficient. For analysis at the 1–100-pmol level, 1-mm-i.d. microbore columns should be appropriate. Capillary HPLC columns of <500 µm i.d. would be preferred for analysis of proteins or peptides at the <1 pMol level. Figure 3 shows a typical on-line microbore HPLC/MS system for the separation and detection of proteolytic digests of proteins. A small fraction of the sample eluted from the column is directed into the electrospray ion source.

Although there are still challenges in capillary HPLC/MS, such as reproducibility between capillary columns, clogging associated with capillary columns, and the requirement for HPLC pumps capable of submicroliter per minute flow rates, recent progress in this field has shown great promise for peptide and protein analysis.\(^{29,33–39}\) Recently, HPLC systems capable of delivering gradients in the 20–1000-nL min\(^{-1}\) flow rate without splitting are commercially available (e.g. Eksigent, Dionex/LC Packing, and Agilent). These systems are especially critical in proteomic experiments that perform large-scale separation of peptides for analysis by a mass spectrometer.

There have been attempts to improve the ESI detection limit. The first is to use a low flow-rate infusion technique to increase the length of mass spectrometric sampling time.\(^{40–43}\) By reducing the diameter of the electrospray needle, flow rates in the nanoliters per minute range (“nanospray”) have been used to achieve low-femtomole levels of detection of peptide and protein samples.\(^{43}\) In a conventional electrospray source, high voltage is used to generate aerosols of charged liquid droplets utilizing flow rates from 10 µL min\(^{-1}\) to 1 mL min\(^{-1}\); the formation of the aerosol is assisted by pneumatic nebulization to produce a stable spray. When the flow rate of the source is reduced to nanoliters per minute, commonly referred to as nanospray, droplets form more readily without the assistance of sheath gas. The ionization efficiency of the nanospray is improved as the flow rate is lowered and thus less volume of the mobile phase passes through the source OR, producing smaller aerosol droplets.

A microfabricated device coupled to ESI is another promising technique that has subfemtomole per microliter detection limits.\(^{44,45}\) Another approach employs capillary HPLC separation methods in conjunction with microelectrospray ionization.\(^{30–32,46–56}\) This approach is capable of on-line peptide separation, which has the advantages of sample purification from contaminants and sample concentration. Research in the design of a smaller microelectrospray needle interface (tip dimension in the range of 1–25 µm), used in combination with capillary HPLC, has shown a significant improvement in sensitivity.\(^{32,55,56}\) Figure 3(a) shows a

The capillary HPLC column was packed with sodium dodecyl sulfate (SDS) removal and POROS (Applied-Biosystems perfusion chromatography) reversed-phase medium. Samples were loaded from an injection valve as shown. A flow rate of 500 nL min$^{-1}$ was maintained by splitting the 150 µL min$^{-1}$ from the HPLC pump, and the effluent was delivered into a microelectrospray needle. Figure 3(b) shows a detailed view of the microelectrospray needle designed by Davis and Lee. The spray needle is pulled from a fused-silica capillary (FSC). The solvent gradient is delivered to the tee using an FSC transfer line, while a 0.3-mm-gold wire is connected to the electrospray potential. This technique can be used for routine analysis of peptide and protein sample amounts ranging from 50 to 500 fmol.

In recent years, multidimensional chromatography based on capillary LC column has been used routinely to analyze highly complex peptide samples, such as samples from large-scale proteomic analysis. Figure 4 shows the multidimensional protein identification technology (MudPIT). This technique has been developed to separate peptide by microcapillary biphasic LC column that is packed with strong cation exchange (SCX) and C$_{18}$ reversed-phase (RP) resin, which is coupled to MS/MS detection (see Figure 4a). In a typical MudPIT
experiment, the complex protein mixture is first digested and loaded onto the 75–100-µm-i.d. fused-silica micro-capillary columns with tip pulled to a 5 µm diameter. By using a series of salt steps with increasing salt concentration (e.g. ammonium acetate), peptides can be eluted from the SCX resin onto the RP resin and then eluted off the RP phase typically using an increasing gradient of organic mobile phase (Figure 4b); the number of salt steps used will depend on the complexity of the sample. The strength of the MudPIT separation is the orthogonality of the two chromatographic phases – the SCX phase separates peptides according to their charge and the RP phase according to their hydrophobicity.

2.5 Experimental Parameters

n-Alkylsilica-based reversed-phased high-performance liquid chromatography (RP-HPLC) is the most common medium for peptide and protein analysis. Typically, peptide and protein samples are eluted with solvent gradients with an increasing concentration of organic component such as acetonitrile. Optimum separations are usually achieved by changing the slope of the gradient, temperature, ionic modifier, or solvent composition. The packing materials used in RP-HPLC are porous silica based and are chemically modified by alkyl chains of variable length. The nature of these hydrophobic ligands is responsible for the chromatographic characteristics of the column. The most common materials used for proteins and peptides are C_{18} (n-octadecyl) and C_{4} (n-butyl). The retention of the proteins and peptides on the reversed-phase columns depends on their hydrophobicity. The shorter chain packing works better for more hydrophobic samples (e.g. proteins), while the longer chain packing C_{18} columns are often used for peptide separation (e.g. peptide mapping). The geometry of the packing material is an important factor for separation. The pore size of the RP-HPLC packing material for protein analysis is usually 100–300 Å and for protein analysis 300–4000 Å. The most common particle diameter in RP-HPLC is 3–5 µm. The conditions for a linear solvent gradient are usually an increase from 5% up to 50–100% organic over 20–120 min, using aqueous acetonitrile solution with 0.1% trifluoroacetic acid (TFA) as the mobile phase. Acetonitrile is widely used because of its high volatility and ultraviolet (UV) transparency. However, an alcohol such as 2-propanol is employed for more hydrophobic peptides or larger proteins. At low pH associated with RP-HPLC, basic residues and the amino terminus exist as cations, so anionic ion-pairing reagents such as TFA can interact with proteins and peptides through a complex with the positively charged groups to enhance separation. However, volatile strong acids such as TFA can cause signal suppression and reduce spray stability in ESI; this is attributed to the high conductivity and increased surface tension. TFA can change the acid–base equilibria in the solution, which makes attracting H^+ more difficult in the ESI process. The effect of TFA on the HPLC/MS
analysis of peptides has been studied.\(^{58–60}\) To improve the quality of electrospray, the surface tension of the effluent can be reduced by mixing the sample flow with a sheath flow of organic solution such as methanol or 2-propanol.\(^{30}\) A different mobile phase comprising formic acid in a 5 : 2 mixture of EtOH and PrOH for capillary HPLC/MS has been suggested.\(^{61}\) To optimize the HPLC/MS performance in the presence of TFA, 10–50-fold signal enhancements have been reported for peptide analysis by adding 75% (v/v) propionic acid–25% (v/v) 2-propanol to the effluent post-column, before the ESI process.\(^{62}\) In addition, non-TFA-requiring columns are available commercially.

3 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY OF PEPTIDES

3.1 Analysis of Peptides by Mass Spectrometry

The sequence information of the peptide is derived from the fragment ions produced in the gas phase. Experimentally, this is achieved in two stages of mass analysis, that is, MS/MS.\(^{63–66}\) The first stage of mass analysis selects the singly charged protonated peptide ion [M + H]\(^+\) of interest. This is followed by CID and the fragment ions produced are analyzed in the second stage of mass analysis. Under favorable conditions, peptide sequence can be interpreted from the tandem mass spectra. At present, the most common mass analyzers for MS/MS include four-sector instruments (mainly for fast atom bombardment mass spectrometry (FABMS)), TOF instruments capable of postsource decay (PSD), Q–Q–Q instruments, and ion trap instruments. The main difference between the four-sector and the other configurations is that four-sector geometry is capable of high-energy collisions (5–10 keV), which can generate extensive side-chain fragmentation, whereas the other modes can only perform low-energy collisions (<100 eV). Figure 5 shows the nomenclature for the fragmentation of a protonated peptide ion and the mechanism for fragment ions formation.\(^{67–70}\) The \(a_n, b_n,\) and \(c_n\) ions are fragment ions with charge retained on the N-terminal portion and the \(x_n, y_n,\) and \(z_n\) ions are fragment ions with charge retained on the C-terminal portion. For example, if the most basic site in the peptide ion is the amide group, in an MS/MS experiment the protonated amide nitrogen will undergo CID and produce fragment ions \(b_2\) and \(y_2.\) The \(b_2\) ion represents the cleavage of the –CO–NH bond between \(R_2\) and \(R_3,\) with the charge retained on the N-terminal fragment. The peptide sequence can be derived from the same type of fragment ions in the tandem mass spectra. Generally, fragment ions \(a_n, b_n,\) and \(y_n\) form continuous series; the ions belong to the same series with the adjacent \(n\) values differing in the mass of the amino acid. The interpretation of peptide sequence involves identifying consecutive pairs of fragment ions with mass peaks that differ by the mass of the amino acid residue, or establishing combined incomplete but overlapping series that are present in the spectra.

3.2 Study of Natural and Synthetic Peptides by High-performance Liquid Chromatography/Mass Spectrometry

A wide variety of naturally occurring peptides, including toxins, neuropeptides, and antigens, have been studied by MS.\(^{71}\) An elegant example of using HPLC/MS for peptides analysis is demonstrated by Hunt et al.’s studies of peptides bound to class I major histocompatibility complex (MHC).\(^{72}\) One of the key events in immune response is the recognition of peptide fragments originating from degradation of foreign proteins by T lymphocytes; peptides bound to class I MHC are derived from the degradation of intracellular proteins. Determination of the sequence information of the antigenic peptide presented on the surface of the cell in association with class I MHC is an important step in designing vaccines and therapeutic treatments for diseases. Information about these peptides can be obtained from studies.
using synthetic peptides and from Edman degradation of mixtures of peptides extracted from class I MHC. However, because HPLC is unable to resolve the complex peptide mixtures, this approach is limited to fractions containing one or two major peptides. To resolve this difficulty, Hunt et al.\(^7\) employed capillary high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS) to study peptides bound to class I MHC HLA-A2.1. In these studies, a nanoscale HPLC column (75 μm × 10 cm) was used to concentrate and deliver into the ESI Q–Q–Q instrument. The detection limit of this method was 30 fmol. Figure 6 shows the tandem mass spectrum of a peptide with \(m/z\) 1121 observed in the separation. Predicted masses for type b and y fragment ions are shown; the ions observed are underlined. Any two consecutive fragment ions differing by the mass of a single amino acid yield the identity of the residue at that position. Residues 5–9 were deduced from b-type ion series, and residues 3–5 from y-type ion series.

In a study of the toxin conopeptides, which comprise highly constrained and multiple disulfide-bonded peptides, HPLC/MS coupled with differential alkylation was used to determine the disulfide connectivity.\(^7,4\)

Another application for HPLC/MS is to evaluate synthetic peptides.\(^5,4\) Synthetic peptides have been used as probes of biological structures, intermediates for enzyme inhibitors, and therapeutic agents, and the automation of solid-phase synthesis has made these peptides more available to users. The peptide synthesis involves the combined processes of synthesis, cleavage, purification, and the final characterization of the product. Analysis of synthetic peptides by a variety of analytical methods has been regularly reported by the Association of Biomolecular Resources Facility (ABRF, http://www.abrf.org).\(^1,4\) The purpose of these studies is to identify optimum methods for characterizing synthetic peptides and to provide data regarding common side-chain reactions and products in peptide synthesis.

Although characterization of postsynthetic peptides can be carried out with analytical tools such as an HPLC profile or an amino acid analysis, MS provides the most direct and most efficient verification of the peptide structure. There are potential problems associated with peptide synthesis, occurring during cleavage of the peptide from the resin and removal of protecting groups from the side chains of the amino acids. Therefore, a single major peak in an HPLC profile of a crude peptide only provides a good indication of the content of the desired product and cannot prove that the structure is correct. Mass spectrometric analysis, on the other hand, allows the identification of the peptide and also the contaminant side products. For characterizing complex mixtures of peptide products that have several major HPLC peaks, a single HPLC/MS run would be very useful to corroborate the assignments of HPLC peaks as the desired peptide or side product. For structural verification of the location of a modification or the identity of a by-product, fragmentation of the peptide is needed. For example, the location of a by-product from modification of the Cys residue of a synthetic peptide has been identified by an MS/MS experiment.\(^4\)

**4 HIGH-SPEED LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY OF PROTEINS**

**4.1 General Strategy of Characterization of Proteins by Mass Spectrometry**

There are three basic types of MS experiments one can perform in a protein analysis:

* mass measurement on intact protein;
* mass measurement on the proteolytic digest of the proteins (peptide mass mapping); and
* amino acid sequencing by MS/MS.

In the first category of experiments, the accurate mass of an intact protein is measured. This information alone could provide sufficient evidence to verify the correctness of a protein sequence and homogeneity of the protein sample and also to detect any chemical or posttranslation

modifications. However, the problems that can be solved using intact protein molecular weights alone depend on the mass accuracy required. For example, to differentiate Asn 114.1 Da/Asp 115.1 Da or Gln 128.1 Da/Glu 129.1 Da substitutions, a mass accuracy of ±0.5 Da is needed. On the other hand, to characterize known glycosylation (e.g. an addition of 162 Da for hexose) or known phosphorylation (an addition of 80 Da), a mass accuracy of ±50 Da would be sufficient. The advancements in the FT/MS capable of extremely high mass accuracy allow applying MS to measure intact proteins and many of the posttranslational modifications. For example, a heterogeneous 42-kDa protein was found to have ragged N-terminus and alkylated Cys residue.

The second category of experiments can achieve the same goal by determining the mass values of the peptide mixture after a proteolytic digest of the protein. Table 2 lists the common cleavage reagents used in protein analysis.

Applications include verification or correction of DNA sequence for proteins, determination of disulfide bridges, and modifications or substitutions of amino acids present in peptides by comparing the predicted molecular weights of the proteolytic peptides with those measured by MS. This method is particularly effective when confirming peptides that are derived from proteins of known sequence, such as recombinant proteins. At present, on-line HPLC/MS analysis of protein digests has become one of the routine methods of analysis in biological MS. Finally, structural information of a protein can be obtained by MS/MS. Conventional methods to determine protein primary structure based on MS involve enzymatic or chemical degradation. The proteolytic peptide mixture is fractionated by RPHPLC and the peptide(s) in the HPLC fractions are analyzed by MS. In CID/MS/MS, gas-phase protonated peptide molecules [M + H]⁺ are generated and selected. These either dissociate spontaneously or dissociate following collisional activation to yield a variety of N- and C-terminal fragment ions. The peptide sequence is obtained from interpretation of the resulting tandem mass spectra. This strategy has been established as a protein sequencing tool by the elegant work of Hunt, Biemann, and others. Although MS and Edman sequencing approach the same level of sensitivity, the former offers advantages in requiring a less demanding purification (separation into individual peptides is preferred in Edman sequencing), efficiency (each Edman sequencing cycle requires at least 20 min), and the ability to identify amino acid modifications. Electro spray ionization tandem mass spectrometry (ESIMS/MS) of tryptic peptides is especially effective. Since there are two charges located on the tryptic peptides, the basic N-terminus and the C-terminus lysine or arginine residue, they generally produce a doubly charged (+2) peptide ion as the base peak. MS/MS of the doubly charged tryptic peptide ions yields primarily singly charged fragment ions, dominated by b- and y-type series ions. The combination of enzymatic digestion and HPLC/MS/MS could provide a very powerful method to characterize protein primary structure.

4.2 Posttranslational Modification of Proteins

Proteins undergo a variety of structural changes after synthesis. As an integral part of the protein structural information, the posttranslational modifications occur immediately after translation of the polypeptide chain. It should be noted that posttranslational modifications cannot be deduced from amino acid sequence. The traditional methods to detect posttranslational modifications include Edman degradation, amino acid analysis, isotopic labeling, and immunochemistry. In recent years, MS and MS/MS experiments have become some of the most powerful methods for the direct identification of these modifications. Applications include the characterization of N-terminal (e.g. formation of formyl and acetyl groups and pyroglutamic acid) and C-terminal (e.g. amidation) blocking groups, new amino acids (e.g. γ-carboxyglutamic acid, and β-hydroxyaspartic acid), disulfide bond formation, glycosylation, and phosphorylation. Since the presence of covalent modifications in proteins produce a change in molecular weight of the modified amino acid, the molecular weight of the protein or peptide that contains the modified amino acid residue, comparison of the experimentally observed intact molecular mass and the calculated mass from amino acid sequence, can reveal mass increase or decrease; the mass difference defines the specific modifications. These intact protein mass measurements can reveal heterogeneous modifications and processing of the protein, from multiple species each corresponding to an individual modification state. Furthermore, the peptide sequencing by MS/MS has the potential to reveal the presence of modification at an individual amino acid residue in proteins. Table 3
summarizes the mass changes due to some of the common protein modifications.

Although in some cases the ability to measure intact protein molecular weights accurately can determine protein modification directly without protein digestion, it is far more common to combine proteolytic digestion, HPLC separation, and MS to achieve this goal. Mass spectrometric strategies and techniques for the identification of modified amino acids in proteins have been reported.\(^{101-105}\)

### 4.3 High-performance Liquid Chromatography/Mass Spectrometry Characterization of Phosphoproteins

Phosphorylation is one of the most common posttranslational modifications of proteins. Protein phosphorylation takes place at specific sites and is frequently reversible. The addition of a phosphoryl group is carried out by specific protein kinases that use ATP as the phosphoryl donor, and it can be removed by phosphatases. Usually, the phosphorylation sites are hydroxyl groups of specific Ser, Thr, and Tyr residues. Short consensus linear sequences of amino acids have been identified as protein phosphorylation sites. However, because phosphorylation happens to folded proteins after protein synthesis is completed, secondary and tertiary structures are also important for determining phosphorylation sites. Therefore, any phosphorylation site predicted from consensus sequence information has to be verified experimentally.

An experimental approach based on Edman sequence analysis has been used for the determination of phosphorylation sites. However, such a method generally requires incorporation of \(^{32}\)P and detection of \(^{32}\)P-labeled peptides.\(^{102}\) Several mass spectrometric approaches have been established for the determination of phosphorylation sites.\(^{103-105}\) The phosphorylation sites have been determined by off-line HPLC and ESIMS.\(^{105}\) In this approach, phosphoproteins are enzymatically cleaved, and the phosphopeptides are then separated and identified by HPLC and ESIMS. When the protein sequence is known, the phosphopeptide is identified by comparing the observed peptide molecular weight with the predicted value based on the sequence. A peptide that has a mass of 80 Da \(+\) HPO\(_3\) \(^-\) higher than the prediction indicates a potential phosphorylation site, and a mass higher by a multiple of 80 Da could indicate several phosphorylation sites.\(^{106}\) An on-line mass spectrometric approach utilizing immobilized metal-ion chromatography coupled to capillary HPLC/MS has been reported.\(^{107}\) Additionally, the potential and limitations of mapping phosphorylation sites using nanospray have also been discussed.\(^{108}\)

A novel LC/MS procedure that utilizes neutral-loss scanning to identify phosphopeptides in a mixture has been described by Covey et al.\(^{109}\) This technique is based on the tendency of phosphopeptides to lose the neutral phosphoric acid moiety. Such a loss indicates phosphoserine and phosphothreonine; these can eliminate \(\beta\)-eliminate after treating the proteolytic digest of the phosphorylated protein with a weak alkali. The phosphopeptide is identified by searching for a decrease of 98 Da (H\(_3\)PO\(_4\)), a loss of 49 Da \((m/z = 98/2 = 49)\) from the doubly charged peptide, and 32.7 Da \((m/z = 98/3)\) from the triply charged peptide ion. Separate experiments are needed to scan for decreases corresponding to each charge state. Carr et al. have developed a simple strategy for HPLC/MS identification of peptides containing phosphate linked to Ser, Thr, and Tyr.\(^{110-112}\) In an HPLC/MS experiment, chromatographic effluent containing a phosphopeptide experiences “in-source” CID, and the phosphopeptide will produce diagnostic fragment ions at \(m/z = 63\) (PO\(_2\)\(^+\)) and 79 (PO\(_3\)\(^-\)) in the negative-ion mode, under a high-collision excitation potential (high OR potential) (see Table 4).

Figure 7(a) shows the UV absorbance chromatogram and single-ion monitoring at \(m/z = 63 + 79\) in the negative-ion detection mode of the selective detection of phosphopeptides in a mixture of six peptides, including Ser-, Thr-, and Tyr-phosphorylated peptides.\(^{110}\)

The effect of OR voltage on the CID of phosphopeptides performed in a quadrupole instrument is shown in Figure 7(b). Notably, no characteristic low-mass fragment

\(^a\) The mass of sugar unit Hex is 162 Da (C\(_{6}\)H\(_{10}\)O\(_{5}\)) and that of carbohydrate fragment ion Hex\(^+\) (C\(_{6}\)H\(_{11}\)O\(_{5}\)) is 163 Da, which is equivalent to the oxonium ion of hexose.
ions occur at a low absolute OR voltage of $-65\,\text{V}$ (low collision energy). However, at a higher OR voltage of $-350\,\text{V}$, the phosphopeptide produces the characteristic fragment ions at $m/z$ 63 and 79. Nevertheless, final determination of phosphorylation sites requires direct sequencing. To take full advantage of the observation of
the marker ions at high OR voltage and the ability to
detect the molecular phosphopeptide ion at a lower OR
temperature, a full-scan LC/MS scheme can be implemented
with a quadrupole instrument, scanning m/z 59–99 with
OR voltage –350 V and m/z 444–2000 with OR voltage
–115 V. In a multidimensional ESIMS approach, LC/MS
is used to identify fractions containing phosphopep-
tide by single-ion monitoring at m/z 79. In the second
dimension, the phosphopeptide-containing fractions are
analyzed by nanoelectrospray to confirm the presence
of phosphopeptide by precursor ion scan and sequence
the phosphopeptide by-product ion scan. It should be noted that matrix-assisted laser desorp-
tion/ionization mass spectrometry (MALDI/MS) can be
used for analyzing phosphopeptides by detecting the
loss of the diagnostic fragment ion. In the positive-ion
mode, the presence of [MH – HPO3]⁺ (–80 Da) and
[MH – H₃PO₄]⁺ (–98 Da) reveal the loss of HPO₃,
and consecutive loss of HPO₃ and H₂O can be used to
locate phosphorylation sites. MALDI/MS can distin-
guish tyrosine phosphorylation from serine and threonine
phosphorylation; phosphorylation of serine and threo-
nine yield abundant [MH – H₃PO₄]⁺ ion and weaker
[MH – HPO3]⁺ ion; phosphotyrosine, however, shows an

4.4 High-performance Liquid Chromatography/Mass
Spectrometry Characterization of Glycopeptides

A carbohydrate unit is attached to glycoproteins by
either an N- or an O-linkage, depending on the attached
amino acid residues (Asn, Thr, or Ser). In the
N-linked structure, the carbohydrate moiety is linked
through the amide N atom of the side chain of an
Asn residue. The attachment site of the Asn-linked
glycopeptide is generally observed in the consensus
sequence Asn–X–Ser/Thr (where X can be any amino
acid except proline); however, only selective consensus
sites are glycosylated. There are three types of common N-
linked carbohydrate structures: complex, high mannose,
and hybrid. The O-linked structures are defined by
the linkage through the O atom of the side-chain hydroxyl
of Thr and Ser residues. No consensus sequence for their
attachment sites has been reported. O-linked structures
are generally less complex than the N-linked structures.
At each attachment site, there is usually a heterogeneous
population of different glycans, a phenomenon referred
to as site heterogeneity. This heterogeneity of the
glycoproteins creates distinct subsets (different structural
classes – complex, hybrid, or high mannose – or different
molecular structures within the same structural class –
differences in number, type, or linkage of the sugar
residues) or glycoforms that have different physical and
biochemical properties.

Chromatographically, RP-HPLC mapping of enzy-
matic peptides of glycoproteins is difficult because
glycopeptides can be present in the peptide map as
broad peaks due to the carbohydrate heterogeneity.
The advent of LC/MS combined with enzymatic
digestion has dramatically changed the characterization
of glycoproteins. The procedure to characterize
glycoproteins by HPLC/MS is as follows: select the appro-
priate enzyme for cleavage, isolate the glycosylation sites
into separate peptides by HPLC, and perform an MS
analysis of the general nature of the glycosylation. If
the primary structure of a protein is known, possible N-
linked glycosylation sites can be predicted on the basis
of a simple enzymatic digestion (e.g. trypsin), together
with the knowledge of the N-linked consensus sequence.
The main objective here is to select a degradation scheme
to isolate peptides containing glycosylation sites. The
separation of the resulting peptides and subsequent mass
analysis can be straightforward, provided the glycopep-
tides do not coelute during chromatographic separation.
In the analysis of large, complex glycoproteins, cleavage
with trypsin may result in a very complex peptide map, in
which glycopeptides can be obscured by the large number
of nonglycosylated peptides. In these cases, digestion with
a different proteolytic enzyme such as Lys–C or Arg–C
produces larger peptide fragments, and can simplify the
detection of glycopeptides. A single HPLC/MS run of
the glycoprotein digest may consist of over 1000 mass
scans, so to interpret and identify the glycosylation sites
using HPLC/MS data requires further methodology
development. An approach to locate glycopeptides in
complex HPLC/MS runs has been suggested by Hancock
et al. In this method, glycoproteins are digested and
then separated and detected by HPLC/MS. The glycopep-
tides are observed as a cluster of negatively sloping ions
in a contour plot of m/z versus retention time from the
HPLC/MS run.

A very specific method was developed for selectively
detecting glycopeptides during the HPLC separation
of glycoprotein digests by Carr et al. In this method,
HPLC/MS is used to locate and differentiate N- and
O-linked glycopeptides, as outlined in Figure 8. The
glycoprotein is cleaved by a protease, producing a mixture
of peptides and glycopeptides. The digestion mixture is
analyzed by three separate experiments: (i) an LC/MS
experiment to locate glycopeptides, (ii) an LC/MS/MS
experiment to identify specifically both N- and O-linked
glycopeptides, and (iii) an experiment to differentiate
N- and O-linked glycopeptides by treating the sample
with PNGase F and performing LC/MS/MS experiments
to identify O-linked glycopeptides. In essence, this
technique is based on the observation of carbohydrate-
specific diagnostic oxonium fragment ions formed by CID
to locate glycopeptides in HPLC/MS (see Table 4). The
O-linked glycopeptides by enzymatic digestion and LC/MS. m/z 292, (NeuAc S.A. Carr, M.J. Huddleston, M.F. Bean, are m/z common low-mass carbohydrate oxonium ions observed (Reproduced by permission of Cambridge University Press from Protein Sci., 2, 183–196 (1993)).

Figure 8 A strategy to locate and differentiate N- and O-linked glycopeptides by enzymatic digestion and LC/MS. (Reproduced by permission of Cambridge University Press from S.A. Carr, M.J. Huddleston, M.F. Bean, Protein Sci., 2, 183–196 (1993)).

common low-mass carbohydrate oxonium ions observed are m/z 147 (dHex+, fucose, or xylose), m/z 163 (Hex+, hexose), m/z 204 (HexNAc+, N-acetylhexosamine), m/z 292, (NeuAc+, N-acetylneuraminic acid), and m/z 366 (HexHexNAc+). The production of oxonium fragment ions takes place in the high-pressure source before the quadrupole mass analyzer (pre-Q1); this experiment requires only a single-quadrupole instrument. Alternatively, in a Q–Q–Q instrument, it can be achieved by selectively detecting only the parent ions that fragment in the Q2 to yield a HexNAc+ ion at m/z 204; both N- and O-linked carbohydrates produce m/z 204. Analogous to the detection of phosphopeptides, the first experiment involves increasing the OR voltage to induce fragmentation during the m/z 150–500 mass scan to observe the carbohydrate oxonium ion fragments, and lowering the OR voltage to a setting that does not cause fragmentation of the glycopeptide ion in the m/z 500–2000 mass scan. This allows for the observation of both the marker oxonium ion fragments and the parent glycopeptides. Figure 9(a–c) shows an HPLC/MS analysis of a trypsin/Asp–N digest of bovine fetuin, which is a 42-kDa glycoprotein containing three N-linked (Asn30, Asn138, and Asn158) and at least three O-linked (Ser253, Thr262, Ser284) glycosylation sites. Although the location of glycopeptides in the HPLC/MS experiment can be determined by examining the total ion current (TIC) trace (Figure 9a) and the reconstructed ion current trace for m/z 204 (Figure 9b), it does not indicate which parent ions produced the marker ions.

For example, there are at least seven components in the peak eluted at about 30 min, labeled Asn81 in Figure 9(c). The second type of experiment can selectively detect glycopeptides by using parent ion scanning (scanning Q1) and monitoring m/z 204, produced by CID in Q2. In the parent ion scan, a specific daughter ion is selected with the second mass analyzer (Q3), and the first mass analyzer (Q1) is scanned over a specific mass range, selecting parent ions that will fragment to yield the fragment ion with the specific m/z value. A parent ion scan is usually employed to screen compounds containing a common substructure. The parent ion scan tandem mass spectrum of the chromatographic peak at 30 min reveals an Asn81 glycopeptide [Asp75–Asn81]. In the third experiment, O-linked glycopeptides are selectively detected by LC/MS/MS analysis of a trypsin/Asp-N digest after it has been treated with PNGase F. There are two enzymes commonly used to determine the sites of carbohydrate attachment by MS. By treating glycoproteins with the enzyme Endo H, the glycosidic bond between the carbohydrate and the N-acetylgalcosamine is cleaved, and the peptide containing a glycosylation site will be 203 Da higher in mass than the corresponding unglycosylated peptide. The enzyme PNGase F, used in this study, hydrolyzes N-linked oligosaccharides. After the PNGase treatment, LC/MS/MS (parent ion scan m/z 204), the only significant remaining signals are Ser253- and Thr262/Ser284-containing peaks (see Figure 9c), and three O-linked glycopeptides were identified.

4.5 Characterization of Recombinant Proteins by High-performance Liquid Chromatography/Mass Spectrometry

The therapeutic value of a recombinant protein is highly dependent on its structure. The protein’s structural properties may vary widely according to the cell types used as the host system and the protein expression conditions. In vitro or in vivo biological activities may depend on the primary structure of the recombinant protein or the extent of posttranslational modifications that are influenced by the specific host expression system. Other factors that may also have an impact on the structure of recombinant protein are cell culture conditions, method of cell harvesting, and the protein purification process. Improvement of analytical methodologies is very important in characterizing the structural details of the recombinant proteins. MS is an analytical method that can be used for the determination of the natural posttranslational modifications (e.g. glycosylation, acylation, phosphorylation, and disulfide bond formation) that are influenced by the host expression systems. It can also determine other modifications such as the carboxylation of lysine (in high concentrations
of urea), the cyclization of the N-terminal glutamine to form pyroglutamic acid, and N- and C-terminal heterogeneity. The modifications, such as deamination of asparagine or glutamine to their acids and the oxidation of methionine or tryptophan occurring during expression or purification, can have a profound influence on the chemical and physical stability of the recombinant proteins.

Many recombinant protein pharmaceuticals are glycoproteins, including antibodies, hormones, growth factors, clotting factors, and cell-surface receptors. The oligosaccharide structure of these recombinant proteins has a direct impact on their half-lives, stability, biological responses, and resistance to proteolysis. The characterization of recombinant human erythropoietin (rEPO) is a well-documented example.\(^{(121-123)}\) EPO is a hormone that stimulates the formation of mature erythrocytes. Off-line RPHPLC coupled with MS has shown that the rEPO from Chinese hamster ovary undergoes both N- and C-terminal processing.\(^{(121)}\) Variation of the carbohydrate structure of rEPO has contributed to the different activities; desialylated rEPO can lose its activity completely. The glycoprotein has three N-linked (N-24, N-38, and N-83) and one O-linked (O-126) glycosylation sites. By combining peptide mapping, deglycosylation, periodate oxidation, and glyceraldehyde methylation, Linsley et al.\(^{(122)}\) were able to study the glycan profiles of four glycopeptides from rEPO by ESIMS. Using HPLC/MS, Rush et al.\(^{(123)}\) identified 52 different N-linked oligosaccharides. HPLC/MS has been used to study another recombinant protein, factor VIII, a glycoprotein involved in the blood coagulation cascade. In these experiments, the oligosaccharide site occupancy and site-specific microheterogeneity were determined by HPLC/MS.\(^{(124,125)}\)

Disulfide bonds in proteins play an important role in protein folding and refolding processes and in maintaining the three-dimensional structure.\(^{(126)}\) Although the amino acid sequence can be deduced from the DNA sequence databases, sequence information alone cannot predict the disulfide bond linkages. Characterization of the

Bean, *Protein Sci.*, 2, 183–196 (1993).)
correct form of the disulfide bridges in recombinant proteins is critical, because an incorrect disulfide linkage may cause loss of biological activity. HPLC/MS tryptic mapping has been used to investigate the disulfide linkages in recombinant factor VIII\textsuperscript{125} and the heparin-binding domain of the endothelial growth factor.\textsuperscript{126} Characterization of the possible disulfide linkage was carried out by comparing the tryptic digest of the intact with the reduced and alkylated proteins. The masses of the unassigned components in the tryptic digest of the nonreduced protein were compared with the calculated molecular weights of all the possible combinations of Cys-containing tryptic peptides.

5 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY ANALYSIS IN THE “PROTEOME” ERA

5.1 Protein Analysis and Proteome

The term proteome was introduced in 1995 to describe a growing field that monitors cellular events by identifying the thousands of proteins that cells produce.\textsuperscript{129} More specifically, proteome can be defined as the protein complement expressed by the genome of an organism. With the completion of genome sequencing projects, DNA sequences of at least 18 organisms are now available, and over 30 more are expected in the near future.\textsuperscript{130,131} Large-scale proteomic projects have been initiated on a number of different organisms. Proteome projects on microbes including \textit{Saccharomyces cerevisiae}, \textit{Haemophilus influenzae}, and \textit{Escherichia coli} are currently in progress, and other projects for more complex organisms are also under way. The central dogma of biology dictates the path of biological information as DNA \textrightarrow RNA \textrightarrow protein. Given the recent advances in techniques such as polymerase chain reaction, cDNA microarray, and the DNA chip, it is now possible to obtain quantitative global information on mRNA expression of cells and tissues. Proteomics can provide information at the level of protein expression (which cannot be predicted from the level of expression of mRNA), and also protein posttranslational modifications. Generally, proteomic analysis represents the analysis of total protein mixture generated from a particular type cell, tissue, or multicellular organisms. The development of several technologies is key to MS-based proteome analysis.\textsuperscript{132–134} First, the separation of proteins extracted from cell or tissue by 2-D/PAGE and identification of gel-separated proteins by MS; and secondly, the analysis of complex peptide mixtures generated by proteolytic digestion of the whole proteome sample (“shotgun proteomics”) by LC and MS/MS. The latter approach has become routine in the proteomics research in the last decade.

5.2 Analyzing Gel-separated Proteins by Mass Spectrometry

The high separation power of gel electrophoresis makes it one of the most useful analytical tools for protein analysis. The size-based sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE) method developed by Laemmli is a standard tool used to separate and characterize proteins with molecular weights of up to 400 kDa. Molecular weights of proteins separated by SDS/PAGE are estimated by comparing the electrophoretic mobility of the protein being analyzed with the mobility of standard proteins with an accuracy of ±10%. For complex proteomic protein samples, 2-D/PAGE is required. The first dimension in 2-D/PAGE is isoelectric focusing, where proteins are separated on the basis of charge. The second dimension is SDS/PAGE, which separates proteins on the basis of their molecular weights. In 2-D/PAGE, thousands of proteins are resolved in a single experiment, and the challenge is to retrieve the information. To study the protein expression pattern, sometimes gel images have to be compared through computer image analysis and database search. Databases of gel images from a number of tissues are available on the Internet (e.g. http://ca.expasy.org/ch2d/2d-index.html). Ultimately, to take full advantage of the resolution of the 2-D/PAGE for protein analysis, the identity of the protein spots on a two-dimensional gel need to be investigated. Traditionally, protein spots on the gel are visualized by Coomassie brilliant blue or silver staining. The identification of proteins is achieved by performing N-terminal or internal Edman sequencing on proteins extracted from the gels, either by electroblotting or electroeluting proteins. However, in addition to other constraints, the Edman sequencing protocol is not rapid enough to process efficiently thousands of proteins separated in a single 2-D/PAGE experiment. Another important factor is sensitivity. The amount of protein material available from a single gel spot is usually in the 1–2 µg range or lower, which sets the minimum sensitivity requirement for any analytical techniques to be feasible. Recently, the development of rapid and highly sensitive MS techniques has changed the protein identification from 2-D/PAGE completely.\textsuperscript{135–139} Figure 10 shows a strategy for identifying proteins separated by 2-D/PAGE by integrating separation, protein digestion, MS, and database search.\textsuperscript{138}

There are three common approaches to performing digestion on gel-separated proteins for subsequent
identification by MS: (i) electroelution of protein from gels and then carrying out enzymatic digestion in solution; (ii) electrotransfer of proteins from gel to membrane and then carrying out an enzymatic digest; and (iii) direct in-gel digestion.\textsuperscript{139,140} The uses of in-gel and on-membrane digestions in conjunction with HPLC/MS are well established.\textsuperscript{141,142} The main consideration for HPLC/MS analysis of in-gel and on-membrane digestions is the compatibility of the chemical reagents used in the protocols. For in-gel digestion, Rosenfeld et al.\textsuperscript{143} reported the method of washing the gels with aqueous acetonitrile–0.02% Tween 20 solution for removal of SDS in Comassie brilliant blue-stained gels. The removal of the detergent is important for HPLC/MS analysis, since its presence is known to interfere with RP-HPLC and because most detergents are ionized by ESI and undergo fragmentation, which can obscure the mass signal from peptides. Analysis of proteins transferred from gels to membranes (e.g. poly(vinylidene difluoride)) usually involves enzyme digestion of membrane-bound protein in the presence of nonionic detergents such as OGP (n-octyl-b-glucopyranoside), Triton X-100, or Tween-20, to assist peptide elution from the membrane and to block enzyme adsorption or peptide readsorption on the membrane.\textsuperscript{144} The efficacies of organic solvents, organic bases, and detergents in dissociating electrophobted proteins from nitrocellulose have been reported by Lui et al.\textsuperscript{145} The use of RTX-100 or PVP-360 can increase peptide recovery, but they can also cause signal suppression problems in HPLC/MS analysis.

Although a very useful technique, 2-D/PAGE has some drawbacks. It is time consuming, difficult to reproduce, and very difficult to automate. Furthermore, low abundant and membrane proteins, which represent a high percentage of cellular proteins and frequently those with important biological functions, are usually not well resolved.

### 5.3 Protein Analysis by High-performance Liquid Chromatography/Tandem Mass Spectrometry

Figure 11 illustrated an early example of large-scale online protein identification by database search that involves HPLC/MS using SEQUEST\textsuperscript{146} to perform database searches with MS/MS fragmentation data.\textsuperscript{146,147} The SEQUEST\textsuperscript{146} program is designed to perform database searches utilizing the fragmentation pattern in a reversed manner. Specifically, the peptide fragmentation pattern acquired by the MS/MS is compared with the calculated fragmentation pattern from every peptide sequence in the database (see Figure 12) (the peptide sequences are first generated from the protein sequences in the database according to user-specified cleavage enzyme(s)). The predicted and the experimental spectra are compared on the basis of matching of peptide fragment ions, their intensities, and the presence of immonium ions. The similarity of the spectra is evaluated by a correlation function that automatically generates a list of possible proteins found, ranked according to the correlation values used by the program. The most important value to be noted is the $\Delta C_n$ score in the SEQUEST\textsuperscript{146} output. The parameter $\Delta C_n$ is an indicator of the quality of the match between the experimental and a theoretical tandem mass spectrum; the match is significant when $\Delta C_n > 0.1$. The advantage of this program is that it does not require manual interpretation of the tandem mass spectra. Mascot is a recently introduced search algorithm, evolved from the molecular weight search (MOWSE) algorithms which performs SEQUEST\textsuperscript{146}-type searches but many times faster.

The usefulness of the HPLC/MS/MS method in proteome research was demonstrated by Ducret et al.\textsuperscript{146}
in a large-scale automated characterization of yeast proteins separated by 2-D/PAGE. Digests extracted from an in-gel digestion were loaded by an autosampler and subsequently injected onto a capillary HPLC system that was coupled to a mass spectrometer. Batches of 40 samples were analyzed in unattended runs during a 24-h period. The rapid scanning rate of the ion trap instrument allows the acquisition of a full-scan mass spectrum every second; it automatically determines the masses of peptide ions in an HPLC run. Target peptide ions were selected and subjected to MS/MS experiments. The resulting spectra were automatically analyzed by SEQUEST™. Figure 11(a) and (b) shows the identification of a protein spot (“spot 59”) separated from yeast cell lysate by 2-D/PAGE and followed by HPLC/MS/MS analysis.

The UV and the ion current traces are shown in Figure 11(a); the tandem mass spectra that were found to correlate with the protein identified in the database are labeled with arrows. The output from the

Figure 12 Overview of mass spectrometry-based proteomics.

SEQUEDT program is shown in Figure 11(b). The spot was identified as ADK_YEAST, a putative adenosine kinase. The protein identity is established by the matches of eight proteolytic peptides with the ADK_YEAST sequence. One peptide is identified as human keratin (K2C_HUMAN), a very common contaminant. For large-scale 2-D/PAGE-separated protein identification, a database search based on tandem mass spectra has the advantage of eliminating ambiguities due to comigrating proteins, which can interfere with peptide mass mapping, and lessens the need for other search constraints such as protein molecular weight, PI (the experimental isoelectric point), or sequence tags. However, it should be noted that this strategy is limited to the identification of proteins existing in the sequence databases.

5.4 Analysis of Large-scale Proteomic Datasets Generated by High-throughput LC-MS/MS

Early on, peptide mass mapping was the most commonly used protein sequence database search method for the identification of 2-D/PAGE-separated proteins.\(^{149-153}\) The method involves in-gel or on-membrane protein digestion by a specific protease (e.g. trypsin). The peptide mixture is extracted from the gel or membrane after digestion for subsequent MS analysis. The experimentally measured peptide masses are compared with all the possible peptide masses calculated from known protein sequences in the databases according to the enzyme specificity. Protein identification usually requires correct matching of observed masses from several proteolytic peptides. The computer algorithms for peptide mass mapping were developed by several laboratories in 1993.\(^{149-152}\)

Usually the user defines the input parameters for the search such as taxonomic category, protein mass range, peptide mass tolerance, possible amino acid modifications (e.g. Met, Cys), and number of missed cleavages. There are several factors that will affect the results of a search using mass mapping. Obviously, the key to the success of mass mapping is the mass accuracy of the molecular weight of the peptides. A mass accuracy of ±3 ppm or better is now achievable. Other factors that will affect the protein identification include the modifications of proteins either artificially or by posttranslational modifications. Some optional modifications such as oxidation of methionine, protection of cysteine residues, and phosphorylation have been incorporated into the programs. Finally, gel electrophoresis may induce protein modifications including cysteine–acrylamide adduct (propionamidocysteine, +71 Da), cysteine–β-mercaptoethanol adduct (+76 Da), and methionine sulfoxide (+16 Da).\(^{154}\)

Rather than using only the information of peptide molecular masses, another strategy for protein identification is to use peptide fragmentation data obtained by MS/MS.\(^{148,155-158}\) The information available from the tandem mass spectra includes the molecular weights of the peptides, the composition of the amino acids, and the sequence of the peptides. Mann and Wilm\(^{155}\) have developed a method using peptide sequence tags (partial manual interpretation of tandem mass spectra to obtain the sequence of two or three amino acids) to search the protein sequence database. Yates et al. have developed a method that allows the search of the protein sequence database by using the uninterpreted MS/MS fragmentation spectra to search the sequence databases.\(^{148,158}\) Since the latter method does not require mass spectral interpretation, it is particularly well suited for automated HPLC/MS.

Presently, the use of LC-MS/MS for analysis of complex peptide mixtures has become one of the main approaches in MS-based proteomics.\(^{132-134}\) Significant progress has been made in the last decade in chromatographic separation, mass spectrometry instrumentation, and protein database search. For peptide mixtures as complex as those generated from proteomic samples (protein from a complex of \(10^2 \text{–} 10^4\) with a dynamic range of at least \(10^5\)),

A single-dimension chromatography does not provide sufficient peak capacity for separation. To increase peak capacity, two-dimensional (strong cation/reversed phase) chromatographic separation of peptide generated by tryptic digestion of proteomic samples have been explored. With subsequent MS/MS and database search, hundreds of proteins can be identified in a single experiment. In automated 2-D LC separation, tryptic peptide mixtures are loaded onto the column and eluted stepwise with a series of salt plugs of increase ionic strength in the first dimension (SCX). The eluted peptides are then separated in the second dimension, the RP phase of the column, and then analyzed by MS/MS. In a typical experiment, thousands of MS and MS/MS peptide spectra are generated. The assignment of such a spectrum to a specific peptide sequence is a critical step in retrieving biological information from such experiments. Indeed, significant progress has been made in this area.

A number of computational tools that have been developed for automatic assignment of peptide fragment ion spectra are summarized in Table 5.159–162 These search tools for MS/MS spectra can be broadly classified into three categories: database searching, de novo sequencing, and hybrid approach.

Sequence database searching of uninterpreted MS/MS spectra is widely used in high-throughput proteomic studies (see Figure 12); SEQUEST and MASCOT are two popular algorithms. In this approach, experimentally acquired MS/MS spectra are compared with predicted spectra from protein sequences database. The majority of the known protein sequences in these databases were obtained by translation of nucleotide sequences data into amino acid sequences. The main difference between different database search tools is the scoring scheme used to quantify the degree of similarity between the compared spectra. Alternatively, peptide sequences can be identified from MS/MS spectra by using de novo sequencing algorithms; however, it requires higher-quality MS/MS spectra and the process is computationally intensive and thus not suitable for high-throughput studies. The hybrid approaches combine the use of short partial peptide sequence tags generated from MS/MS spectra and de novo algorithms, and error-tolerant database searching.

Peptide sequence assignments for large amount of data generated in these high-throughput experiments still present significant challenges. To address some of the technical issues, there have been efforts to improve the understanding of gas-phase peptide ion fragmentation process, processing MS/MS spectra before submitting for database search, and refining scoring schemes and search algorithms to diminish false positives and false negatives. One such advancement is the development of spectral library-searching method for peptide identification from MS/MS spectra.163 The concept of library searching – to infer the chemical structure of unknowns by comparing the observed EI spectra with a compiled spectral library from the characteristic fragmentation patterns – has been used successfully by analytical chemists for a very long time. The same approach has been used to develop the software program SpectraST, a tool that performs spectral library search on peptide MS/MS spectra against compiled spectral libraries for peptides.

Hydrophilic-interaction liquid chromatography (HILIC) has been introduced as a highly efficient chromatographic technique for the separation of a wide range of solutes. A hydrophilic stationary phase is eluted with a hydrophobic mobile phase whereby retention of solutes increases with the hydrophilicity of solutes. Bound solutes are eluted by decreasing the hydrophobicity of the mobile phase. Mixed mode effects based on hydrophilic and ionic interactions can also be exploited by proper selection of the stationary and the mobile phase. Typically, the order of elution is the opposite of that obtained by reversed-phase chromatography (RPC). HILIC is particularly interesting for solutes which are difficult to chromatograph on conventional reversed-phase materials. This review focuses on the application of HILIC to the separation of amphipathic α-helical peptides, the analysis of protein glycosylation, phosphorylation, and acetylation, and to the removal of detergents from membrane proteins.

1 INTRODUCTION

It is axiomatic in biological sciences that understanding the function of proteins or peptides requires determination of their structures. Advances in chemical technology, the development of cDNA chip technology and the accumulation of DNA data banks make it possible to obtain a global and quantitative picture of mRNA and protein expression in model organisms such as the yeast *Saccharomyces cerevisiae*. Changes in relative abundance of mRNAs and proteins in response to environmental changes or in response to alteration of the expression of transcriptional factors have been investigated at a genome-wide level.

Instrumental to these breakthroughs was the development of interfacing high-resolution protein separation such as two-dimensional (2-D) gel electrophoresis with various chromatographic techniques and mass spectrometry (MS) for high sensitivity detection and analysis of peptides and proteins. Reversed-phase high-performance liquid chromatography (RP-HPLC) is one of the most widely used chromatographic separations. The combination of RP-HPLC and electrospray ionization (ESI) represents a particularly attractive configuration for the on-line analysis of complex peptide mixtures. Automation of chromatography and mass spectral analysis in combination with powerful data base searching algorithms allow the identification of hundreds of proteins separated by 2-D gel electrophoresis. As the number of protein sequences compiled in databases increased, it has become feasible to match a gel spot to a known protein without extensive sequence information. In favorable cases, as few as two peptides are sufficient to identify proteins in gels at the low picomole level, even when several unresolved proteins are present.

As powerful as these methods are for protein identification, the structure and the function of proteins is in many cases critically regulated by modifications. Co- and posttranslational modifications such as phosphorylation, sulfation, glycosylation, and N-terminal modifications are means to regulate the cellular distribution and function of proteins and are of particular importance in cell signalling. To date, approximately 250 physiological covalent modifications are known. For the characterization of such modifications, various analytical techniques such as radiolabeling followed by chemical cleavage (e.g. Edman degradation) are often applied to unravel the nature of such modifications. Common to all of these experiments is the need to chemically, or enzymatically, cleave the protein into smaller pieces, isolate the fragment of interest and determine its precise location and nature of modification. The majority of such peptide separations is carried out by RP-HPLC. However,
the nature of the modification, or the tactical considerations leading to the isolation of peptides carrying the modification may necessitate the use of alternative chromatographic techniques.

Since its introduction in 1990 by Alpert\(^{15}\) HILIC has been used in a number of applications to solve chromatographic problems not amenable to conventional types of chromatographies, such as ion-exchange, or RPHPLC. This article is intended to give a selection of recent applications of HILIC in the field of bioanalytical chromatography in the hope that they can be taken as a basis to solve chromatographic problems other than the ones outlined below.

### 2 THE “HYDROPHILIC” EFFECT

In the search for new stationary phases which can complement RPC, the hydrophilic strong-cation-exchange (CEX) material PolySulfoethyl A was introduced in 1988.\(^{16}\) Retention of solutes in mobile phases containing low concentrations of acetonitrile on such PolySulfoethyl A supports is mainly governed by charge effects due to the electrostatic interactions between solutes and the stationary phase. Thus, elution of peptides, for example, is governed by the number of basic residues when chromatography is performed at pH 3. Typically, columns of this material are eluted with a salt gradient.

The selectivity of the stationary phase changes markedly when the proportion of organic solvent is increased above 70%: retention of solutes is drastically increased. These data suggest that an increase in organic solvent leads to a higher sensitivity of the stationary phase to interact with hydrophilic residues of peptides. If this were the case, elution of solutes should occur according to increasing hydrophilicity. When the elution behavior of a series of peptides with increasing hydrophobicity was compared between RPC and HILIC, it was shown that the order of elution between the two modes of chromatography was reversed, strongly suggesting that the interaction of solutes and the stationary phase is indeed governed by hydrophilic interactions.\(^{17}\)

Therefore, in contrast to “normal-phase” chromatography, where solutes are adsorbed to a polar stationary phase and elution is promoted by increasing the polarity of the mobile phase, the combination of a hydrophilic stationary phase and hydrophobic, mostly organic phases was designated as HILIC.\(^{15}\)

As an example, the adsorption behavior of amino acids on two different, polar stationary phases, PolySulfoethyl A and PolyHydroxyethyl A is shown (Figure 1a). At pH 2.8, no amino acids are retained to a significant extent on PolyHydroxyethyl A in the absence of acetonitrile, whereas the basic amino acids Arg, His, and Lys are slightly retained on PolySulfoethyl A, probably due to ionic interactions between the negatively charged sulfonic group and the positively charged side chains of the amino acids. A strong increase in retention of all amino acids occurs when the acetonitrile concentration is raised above 60%. Interestingly, the most polar amino acids Arg, His, and Lys show the most pronounced increase in retention, arguing that the interactions between the stationary phase and the solutes are indeed of hydrophilic nature (Figure 1a). Elution...
of bound amino acids from PolySulfoethyl A occurs in the order of their hydrophilicities: the most unpolar amino acids Phe, Leu, Met, Pro, and Val elute first, followed by the more polar amino acids (Figure 1b). Also, when compared to RPC, the order of elution is reversed: the amino acids Met, Leu, Ile, Trp, and Phe eluting last from reversed-phase columns are the first to elute from PolySulfoethyl A or PolyHydroxyethyl A, again arguing that HILIC exploits interactions based on hydrophilicity in the chromatographic process.

The mechanism by which solutes interact with a hydrophilic stationary phase at high organic solvent concentration is not fully understood. In simple terms, HILIC can be regarded as a variant of normal-phase chromatography where retention is proportional to the polarity of the solute and inversely proportional to the polarity of the mobile phase. However, in contrast to normal-phase chromatography, there is evidence that the mechanism of HILIC involves partitioning between the hydrophobic mobile phase and a layer of mobile phase which is enriched with water and is partially immobilized on the stationary phase.\(^{(15)}\)

From a practical point of view, the chromatographer now has the choice of two well defined stationary phases for HILIC: PolySulfoethyl A and PolyHydroxyethyl A. The former matrix can be used primarily as a CEX material, whose polar matrix is well suited for solving specific separation problems such as the isolation of C-terminal peptides,\(^{(18)}\) disulfide-linked peptides,\(^{(19)}\) and pyroglutamyl-terminated peptides\(^{(20)}\) from protein digests. Interesting applications arise, when the two properties, ion-exchange- and hydrophilic interactions of the matrix at high concentrations of organic solvent, are exploited simultaneously. The latter matrix (PolyHydroxyethyl A) is more hydrophilic than PolySulfoethyl A and should therefore be used for substances which fail to bind to PolySulfoethyl A. Although not evident from its structure, in addition to the hydrophilic interactions the PolyHydroxyethyl A support also exhibits weak ionic interactions.\(^{(17)}\) Therefore, the ‘ideal’ sorbent exhibiting solely hydrophilic interactions has yet to be developed. However, these mixed-mode HILIC/ion-exchange (HILIC/IEX) interactions allow a great deal of chromatographic flexibility. The CEX properties of the support separates solutes based on net positive charge and this separation mode is overlaid by the presence of acetonitrile overcoming undesirable hydrophobic interactions with the sorbent while promoting favorable hydrophilic interactions. Thus, mixed-mode separations are typically carried out with linearly increasing salt gradients at pH 3, with mobile phases containing 15–80% acetonitrile. On the other hand, separations exploiting primarily hydrophilic interactions require gradients of decreasing organic solvent (also termed ‘inverse’ gradients) or increasing salt. Which of the two types of separations is to be chosen depends on the goal of the individual separation process and has to be found on a trial basis.

3 APPLICATIONS

3.1 Hydrophilic Interaction/Cation-exchange Chromatography for Separation of Amphipathic α-Helical Peptides

A particularly illustrative example of HILIC combined with ion-exchange chromatography was recently published by Mant and coworkers.\(^{(21)}\) The goal was to assess the relative contributions of α-helical structural elements on the influence of chromatographic behavior during RPC and HILIC. A series of amphipathic α-helical peptides was synthesized whose amino acids in the centre of their hydrophilic or hydrophobic faces were varied to assess their relative contributions for their retention behavior during HILIC or RPC.

In all of these studies, HILIC was carried out in the mixed-mode where hydrophilic and ionic interactions are superimposed. Consequently, the strong CEX material PolySulfoethyl A was operated at pH 3.0 to ensure a net positive charge of the peptides by protonation of acidic and basic side chains (the pK\(_a\) value of glutamate and aspartate is approximately 4.5, and all basic amino acids are fully protonated). Also, pH 3 leaves a net negative charge on the sulphonate CEX functional group (pK\(_a\) ~ 1–1.5). Hence, the use of 20 mM aqueous triethylammonium phosphate (TEAP) in the presence of NaClO\(_4\) was chosen. The choice of salts for elution of ionically bound substances is of particular importance if hydrophilic interactions are to be exploited at relatively high organic solvent concentrations. NaClO\(_4\) is suitable for this purpose due to its excellent solubility characteristics in the presence of high concentrations of organic solvent (up to 400 mM NaClO\(_4\) in 80% acetonitrile).

To study the effect of amphipathicity on the retention behavior, two series of peptides were chromatographed: the two nonamphipathic analogs Ac-Glu-Glu-Ala-Lys-Ala-Lys-Ala-Glu-Ala-Glu-Lys-NH\(_2\) (naA) and Ac-Glu-Glu-Leu-Lys-Leu-Lys-Leu-Glu-Glu-Leu-Glu-Leu-Glu-Leu-Glu-NH\(_2\) (naL) and the two amphipathic analogs Ac-Glu-Ala-Glu-Lys-Ala-Lys-Ala-Glu-Ala-Lys-Ala-Lys-Ala-Lys-Ala-Lys-Ala-Lys-Ala-Lys-NH\(_2\) (AA9) and Ac-Glu-Leu-Glu-Leu-Leu-Glu-Leu-Glu-Leu-Glu-Leu-Glu-Leu-Glu-Leu-Glu-Leu-Glu-NH\(_2\) (LL9). The periodic distribution of the non-polar residues alanine in AA9 and leucine in LL9 ensures a wide hydrophobic face on the amphipathic helix,
whereas the hydrophilic face is made up of lysine and glutamic acids. Furthermore, the peptide pairs naA and AA9, and naL and LL9, respectively, have the same amino acid composition, but different amino acid sequences. RPC of the mixture of the α-helical peptides AA9 and LL9 and their nonamphipathic counterparts naA and naL not only separated all four peptides, separation also occurred between the nonamphipathic and their amphipathic analogs (Figure 2a). For both pairs of peptides (AA9/naA and LL9/naL) the amphipathic analogs AA9 and LL9 eluted later in the gradient than their nonamphipathic analogs AA9 and LL9. This is in accordance with findings previously reported that conformational effects can have a profound effect on the retention behavior of peptides on RPC. Upon binding to a hydrophobic stationary phase, α-helical structures are stabilized and due to the preferred binding domain created by the non-polar face of an α-helix, they are more retentive than peptides having the same composition (and therefore the same overall hydrophobicity) but lacking secondary structural elements creating such preferred binding domains.

In the absence of any conformational effects, peptide retention between HILIC and RPC is reversed, which means that the most hydrophilic peptides are eluted last during HILIC and first during RPC. If adsorption of peptides to the stationary phase occurs predominantly through preferred binding domains formed by secondary structural elements such as α-helices, one would expect in HILIC that amphipathic peptides bind to the hydrophilic stationary phase via their polar face, and the unpolar face will generally be oriented away and will have a lesser effect on retention if these residues were distributed evenly throughout the helix. This is clearly demonstrated due to the fact that the two amphipathic peptides LL9 and AA9 eluted later during HILIC/EX than their nonamphipathic counterparts naL and naA (Figure 2b). Also, within the corresponding amphipathic and nonamphipathic analogs, the less polar Leu analog elutes earlier than the Ala analog. These results clearly demonstrate that binding of peptides in the HILIC/EX mode occurs through interactions between hydrophilic portions of peptides and the hydrophilic surface of the stationary phase and that these interactions can become stronger when secondary structural elements such as α-helices form preferred binding domains.

A distinct advantage of HILIC lies in the fact that due to the high content of organic solvents used to promote hydrophilic interactions, extremely hydrophobic peptides can be chromatographed under more favorable conditions than by RPC. Some examples are the extremely hydrophobic amphipathic α-helical peptides LL7 (Ac-Glu-Leu-Glu-Lys-Leu-Leu-Leu-Glu-Leu-Lys-amide), LT7 (Ac-Glu-Leu-Glu-Lys-Leu-Leu-Thr-Glu-Leu-Glu-Lys-Leu-Lys-Leu-Glu-Leu-Lys-amide), LV7 (Ac-Glu-Leu-Glu-Lys-Leu-Leu-Val-Glu-Leu-Glu-Lys-Leu-Lys-Leu-Glu-Leu-Lys-amide), and LS7 (Ac-Glu-Leu-Glu-Lys-Leu-Leu-Ser-Glu-Leu-Glu-Lys-Leu-Lys-Leu-Glu-Leu-Lys-amide). These peptides have a long hydrophilic face formed by the acid and basic amino acids at positions 1, 3, 4, 8, 10, 11, 14, 15, 17, and 18. In addition, the center of the polar face formed by amino acid seven is varied in terms of its polarity from an unpolar leucine to a polar serine residue. The hydrophobic face is formed by the extremely unpolar amino acid leucine at positions 2, 5, 6, 9, 12, 13, and 16. Thus, the preferred binding sites for the interaction between reversed-phase supports is formed by identical
sequences in all four peptides and should therefore result in coelution of the peptides during RPLC. Indeed, coelution of all peptides during RPC occurred at pH 2 and 3 (Figure 3). Obviously, substitutions in the hydrophilic face has little effect on the retention behavior of the peptides. The increased retention time at pH 3 is either a consequence of the binding of the negatively charged ClO$_4^-$ ion to the positively charged lysine groups of the peptides, or might be caused by enhanced hydrophobic effects between the peptides and the stationary phase induced by the relatively high concentration of the salt present in the mobile phase.

In contrast to RPC, all four peptides were well separated by HILIC/IEX (Figure 3). Since the four peptides have all identical net positive charges and therefore, act equally strongly with the ion exchange matrix, the separation is a consequence of the different substitutions introduced into the hydrophilic face of these peptides. As previously observed, the elution order follows the decreasing hydrophobicity with the leucine analog eluting first, followed by the Val, Thr, and Ser analogs, underscoring the fact that the interaction with the hydrophilic stationary phase occurs predominantly through the hydrophilic face present in these amphiphatic peptides. Also note the dramatic improvement of peak shape in HILIC/IEX when compared to RPC, indicating that HILIC might be a better alternative for the chromatography of extremely hydrophobic peptides.

3.2 Analysis of Protein Glycosylation by Hydrophilic-interaction Liquid Chromatography

Expression of proteins for therapeutic use in mammalian cell culture systems has created demands for extensive analytical characterization of the recombinant product. For many glycoproteins, the carbohydrate moieties endow their polypeptide portion with important physical properties such as conformational stability, protease resistance, charge, and water binding capacity. Interest in the biological roles of the carbohydrate chains of glycoproteins has been intensified because of interesting examples of their importance as recognition markers for protein targeting and cell–cell and cell–matrix interactions. Characterization of the glycosylation pattern of a protein is challenging in as much as glycosylation sites can be occupied with carbohydrates of different structures. Traditionally, characterization of glycosylation sites is carried out by generating glycopeptides from enzymatic digests of glycoproteins which are usually separated by RPHPLC. However, because the hydrophobic stationary phase exploits interactions with hydrophobic residues of the peptide chain, separation of peptides having the same glycosylation site, but carrying different oligosaccharide structures, is not always successful. In contrast, it can be assumed that the high initial concentration of organic solvent used in HILIC promotes interactions primarily between the hydrophilic stationary phase and the hydrophilic oligosaccharide moiety of a glycopeptide, therefore exploiting interactions more favorable for the separation of differentially glycosylated peptides. This was convincingly demonstrated by analyzing the glycosylation pattern of interferon-γ expressed in Chinese hamster ovary cell culture. The two tryptic glycopeptides containing N-linked carbohydrates at Asn$_{25}$ and Asn$_{97}$ were first isolated by RPHPLC and further analyzed by hydrophilic interaction chromatography on a Polyhydroxyethyl A column at pH 6.0 in 85% acetonitrile. Bound glycopeptides were eluted with a gradient of decreasing acetonitrile and increasing NaClO$_4$ concentration, thus separation by HILIC was carried out in mixed-mode (ionic-overlaid with hydrophilic interactions). Both seemingly pure glycopeptides isolated by RPC were further resolved by HILIC into a number of peaks assumed to contain different oligosaccharide structures (Figure 4). By measuring the mass of each of the components by matrix-assisted laser
Figure 4 HILIC of tryptic glycopeptides of Asn25 (a) and Asn97 (b) from recombinant human γ-interferon isolated from chinese hamster ovary cell cultures. Chromatographic conditions: column (1 × 150 mm) packed with PolyHydroxyethyl A, solvent A: 10 mM triethylamine, pH 6.0, 85% acetonitrile, solvent B: 10 mM triethylamine, pH 6.0, 25 mM NaClO4, 20% acetonitrile, 60 min gradient from 100% solvent A to 100% solvent B at a flow rate of 50 µlm in−1. Peptide monitoring was at 220 nm. (Reproduced from Zhang and Wang.25/ with permission of Elsevier Science © 1998.)

desorption/ionization/time-of-flight (MALDI/TOF) MS the glycan structures for the two glycopeptides were identified by comparing the mass difference between the observed mass of the glycopeptides and the known mass of its peptide fragments. The most abundant species on the Asn25 peptide were fully sialylated bi- and triantennary glycans, containing one fucose unit, whereas the Asn97 glycopeptide contained mostly sialylated biantennary glycans lacking fucose (Figure 5). From the structures shown in Figure 5(a), it is apparent that the sialic acids have the most profound effect on retention of glycopeptides during HILIC: the glycopeptides are eluted according to their degree of sialylation (monosialo elutes first, tetrasialo last). Whereas in RPC separation the peptide portion of the glycopeptides is exploited for separation, HILIC offers an alternative separation method for the resolution of differentially glycosylated peptides by exploiting contact regions other than the peptide backbone.

Another observation interesting to note is that HILIC is able to separate different glycans with the same number of sialic acids. For example, the bisialo biantennary glycopeptide (peak 6, Figure 4b) elutes earlier than the bisialo triantennary glycopeptide (peak 7, Figure 4b). Also, two glycopeptides with the same mass elute in two separate peaks (peaks 3 and 4, Figure 4b) which suggests that two monosialo biantennary structures but with different branching (MAN(α1–3) or MAN(α1–6)) can be separated by HILIC. Therefore, HILIC not only holds great promise for further research on separation of oligosaccharide chromatography, it can also provide a means for quantitative monitoring of site-specific glycosylation in process monitoring of proteins produced for pharmaceutical production.

3.3 Analysis of Protein Phosphorylation and Acetylation by Hydrophilic-interaction Liquid Chromatography

Histones belong to a family of proteins which are thought to play an important role in organizing and modulating the structure of eukaryotic chromatin. They become phosphorylated, acetylated and ubiquitinated and it is believed that reversible posttranslational modification of histones are associated with dynamic changes in chromosome packaging during cell cycle. To be able to study the relationship between histone phosphorylation and chromatin structure/function, a system is needed in which precisely defined phosphorylated H1 histones and DNA sequences can be reconstituted. A number of possible strategies exist to resolve and isolate differentially phosphorylated proteins, such as 2-D polyacrylamide gel electrophoresis (PAGE), ion-exchange chromatography, or capillary electrophoresis. Because phosphorylation increases the polarity of a protein due to the presence of the phosphate group, HILIC offers an alternative to the above mentioned separations.

In their studies to separate modified histone H1 subtypes into single components, Lindner et al.26/ developed a two-step high-performance liquid chromatography (HPLC) procedure by combining RPHPLC and HILIC. In a first step, separation of whole linker histones were isolated from exponentially growing Raji cells (a cell line originally derived from patients with Burkitt’s lymphoma) and separated into two components, H1.1 and H1.2 (Figure 6a). Capillary zone electrophoresis (CZE) of the H1.1 fraction separated the seemingly pure protein into four distinct components (Figure 6b), presumably consisting of nonphosphorylated (p0), singly- (p1), doubly- (p2) and a small amount of triply- (p3) phosphorylated histone H1. Treatment of the H1.1 pool with alkaline

(a) Figure 5 Oligosaccharide structures for Asn25 (a) and Asn97 (b) from recombinant human γ-interferon which were separated by HILIC into the peaks shown in Figure 4. The structures were identified by measuring the masses of the peptides present in the individual peaks and comparing them with the expected masses for a given oligosaccharide structure. (Reproduced from Zhang and Wang with permission of Elsevier Science © 1998.)

phosphatase followed by CZE showed that the p1, p2, and p3 components were converted to p0 and therefore indeed represented singly-, doubly-, and triply phosphorylated H1 histones. CEX chromatography of the H1.1 pool on a PolyCAT A column (a weak CEX material with a bonded coating of polyaspartic acid) at pH 3.0 with a linear gradient of sodium perchlorate was unable to resolve the differentially phosphorylated histones into single components. Since phosphorylation of histone H1 takes place exclusively in hydrophilic N- and C-terminal regions
PEPTIDES AND PROTEINS

Figure 6 (a) Separation of histones from Raji cells by RPLC. Column: C4 reversed-phase Nucleosil 300-5 (8 × 250 mm, 5 µm particle size, 300 Å pore size). Solvent A: 0.1% TFA, solvent B: 70% acetonitrile, 0.1% TFA. Flow: 1.5 ml min⁻¹. Gradient: linear from 53:47 solvent A:solvent B to 45:55 solvent A:solvent B in 35 min. Approximately 200 µg total protein was applied. (b) CZE of histone H1.1 before (i) and after (ii) treatment with alkaline phosphatase. p0, p1, p2, and p3 denote unphosphorylated, singly-, doubly-, and triply phosphorylated H1.1 histones. (c) HILIC of multiply phosphorylated histones H1.1 isolated by RPLC (s. panel A). The column used was a PolyCAT A (4.6 × 200 mm) which was developed at 1 ml min⁻¹ with a two step gradient from solvent A (10 mM triethylamine-methanephosphonic acid, pH 3.0, containing 70% acetonitrile) to solvent B (10 mM triethylamine-methanephosphonic acid, pH 3.0, 70% acetonitrile, 1 M NaClO₄). Solvent B was increased from 0 to 60% B in 5 min and from 60% to 100% B in 30 min. Protein load was between 20–150 µg. p0, p1, p2, and p3 denote unphosphorylated, singly-, doubly-, and triply phosphorylated H1.1 histones. (d) HILIC of H1.1 histones dephosphorylated with alkaline phosphatase. Chromatography was performed as described in (c). p0 and p1: unphosphorylated and monophosphorylated histone H1.1. (Reproduced from Lindner et al. with permission of Elsevier Science © 1997.)

flanking a hydrophobic central domain, the authors speculated that HILIC should be better suited to exploit interactions between the hydrophilic domains of the protein and the stationary phase. Indeed, increasing the acetonitrile concentration from 40% to 70% to promote hydrophilic interactions with the PolyCAT A support resulted in the separation of the H1.1 pool into four distinct peaks, when elution was carried out with a salt gradient at pH 3.0 (Figure 6c). Again, the use of NaClO₄ and triethylamine-methanephosphonic acid to adjust the pH of the solvent system is dictated by the use of such high concentrations of acetonitrile in the solvent system. Treatment of the H1.1 pool by alkaline phosphatase followed by HILIC led to the disappearance of the doubly- and triply phosphorylated H1.1 with some residual mono phosphorylated H1.1 due to incomplete removal of phosphate by the enzyme (Figure 6d). The order of elution of these differentially phosphorylated species during HILIC follows the degree of phosphorylation with the nonphosphorylated protein eluting first, followed by the singly-, doubly-, and triply-phosphorylated protein, therefore following the order of hydrophilicity.

Similar observations with respect to the separation of acetylated histone H4 were made from the same team. Acetylation of the N-terminal domains of the so-called core histones H2A, H2B, H3, and H4 have been described, but their biological implications are not well understood. To be able to study nucleosome and chromatin structure–function relationships of histone acetylation, chromatographic procedures have to be developed which yield defined acetylated histones. RPH-PLC has proved to be successful in separating histones, but failed to resolve posttranslationally modified histones. Therefore, initial separation of whole histones is first carried out to separate them into linker histone subtypes (H1o, H1b, H1a, H1e + H1d, H1c) and core histones (H2B, H2A, H4, and H3) (Figure 7a). Among them, histone H4 has been shown to occur in multiply acetylated forms. Although histone H4 appeared to be pure based on the peak shape, the protein could be further separated...
Ion-exchange chromatography, although potentially well suited to resolve proteins whose net positive charge decreases upon acetylation, was unable to separate the various acetylated forms of histone. Since upon acetylation, not only the net positive charge decreases, but also the hydrophilicity, HILIC was investigated as a possible separation method for the differentially acetylated histone H4. Elution of H4 on a SynChropak CM300 CEX column at pH 3.0 with a salt gradient in the presence of acetonitrile successfully resolved the proteins into three different species consisting of the di-acetylated, mono-acetylated and non-acetylated histone. The decrease of hydrophilicity brought about by acetylation is in good agreement with the observed order of elution, with the most hydrophilic species (non-acetylated histone) eluting last, preceded by the mono-, and di-acetylated histone, respectively (Figure 7b). Interestingly, hyperacetylation brought about by butyrate treatment of Friend erythroblast cells could easily be followed by HILIC. Butyrate treatment increased modification of histone H4 by the addition of two more acetate groups which could all be separated by HILIC (Figure 7c). Furthermore, the extent of modification occurring in vivo can be monitored with the HILIC method, since a close correlation of the observed peak heights of the various acetylated proteins exists between HILIC and CZE (compare Figure 7c and d). It should also be noted that the order of elution of the hyperacetylated H4 histones is reversed between HILIC and CZE. Since CZE separation is mainly depending on charge effects, elution of the non-acetylated histone occurs first, followed by the increasingly acetylated forms which contain decreasing net positive charges due to increasing acetylation.

Figure 7 (a) RPLC of whole histones from Friend erythroblast cells. Column: C4 Nucleosil 300-5 (8 × 125 mm, 5 µm particle size, 300 Å pore size). Solvents: A: 0.1% TFA, 10% ethylene glycol monomethyl ether, B: 70% acetonitrile in A. The multistep gradient was developed at 1 ml min⁻¹ according to the following program: from 40 to 61% (45 min), from 61 to 64% (35 min), from 64 to 74% (2 min), isocratic at 74% for 9 min and from 74 to 100% in 10 min. 250 µg total protein was injected. (b) HILIC of the histone H4 pool isolated by RPLC (panel A). The column used was a SynChropak CM300 (4.6 × 250 mm, 6.5 µm particle size, 300 Å pore size) developed at 1 ml min⁻¹ with the following solvents: A: 15 mM triethylamine phosphate, pH 3.0, containing 70% acetonitrile, solvent B: solvent A containing 0.68 M NaClO₄. The concentration of solvent B was increased from 0 to 10% B during 2 min and from 10 to 40% B during 30 min. (c) HILIC of H4 histones from butyrate treated Friend erythroblast cells. Column and chromatographic conditions as in panel B. ac0–ac4 denote nonacetylated, singly-, doubly-, triply-, and quadruply-acetylated histone H4. (d) CZE of hyperacetylated histone H4 from butyrate treated Friend erythroblast cells. ac0–ac4 are nonacetylated, singly-, doubly-, triply-, and quadruply-acetylated histones H4. 3.4 Removal of Detergent from Membrane Proteins

Structural characterization of membrane proteins is often hampered by their hydrophobic nature and tendency to aggregate. A particularly useful detergent in this respect is sodium dodecylsulfate (SDS). Although of strongly denaturing character, SDS is often the last resort to solubilize extremely hydrophobic proteins. The use of SDS however, poses particular problems when primary structure determinations are to be carried out: it inhibits enzymatic digestion of SDS-coated proteins, and residual detergent severely affects subsequent fragment separation by RPHPLC.\(^{28}\) In this context, it is interesting to note that a procedure for detergent removal has been suggested by Simpson et al.\(^{29}\) which can be regarded as an early type of hydrophilic interaction chromatography. By investigating a variety of reversed-phase supports, it was noted proteins bind to certain reversed-phase packings at high concentrations of organic solvent. Bound proteins can then be eluted with a decreasing gradient of organic solvent. The authors attributed this finding due to the presence of residual silanol groups which create a hydrophilic environment for proteins to bind. Such behavior is typical for proteins whereas small molecular weight compounds are not retained at such concentrations of organic solvent. This offers a convenient method for desalting proteins into volatile buffer systems for subsequent structural characterization such as automated Edman degradations and MS.

![Figure 8](image-url) Chromatography of polypeptides on PolyHydroxyethyl A. (a) Gel filtration of ovalbumin (1, 25 µg), synthetic decamer GKEGLRFDMKGA (2, 25 µg), and tryptophan (3, 5 µg). The column (4.6 × 200 mm) was packed with PolyHydroxyethyl A (5 µm particle size, 200 Å pore size). The column was developed at 0.5 ml min\(^{-1}\) in 50 mM formic acid containing 20% n-propanol. (b) Gradient elution of a mixture of ovalbumin (1, 10 µg), cytochrome c (2, 10 µg), and bovine serum albumine (3, 10 µg) at 0.5 ml min\(^{-1}\) with a step gradient from 75% n-propanol, 50 mM formic acid (solvent A) to 50 mM formic acid (solvent B) according to the following program: 5 min 0% B, 5–10 min 20% B, 10–15 min 40% B, 15–20 min 60% B, 20–25 min 80% B, and 25–30 min 100% B. (c) Dependence of capacity factor k’ for cytochrome c on the composition of the mobile phase. The effluent was monitored at 280 nm.

![Figure 9](image-url) HILIC of electroeluted mitochondrial 45 kDa outer membrane protein. (a) 20 µg of electroeluted 45 kDa outer membrane protein was injected onto a PolyHydroxyethyl A column which had been equilibrated in 70% n-propanol, 50 mM formic acid. Elution of the protein was carried out as described in Figure 8(b). The inset shows an SDS polyacrylamide gel with molecular weight standards (left) and the 45 kDa outer membrane protein eluted from the column (right). (b) Elution of SDS from the PolyHydroxyethyl A column tested with Fuchsin red.
A similar method for detergent removal was developed based on the hydrophilic stationary phase PolyHydroxyethyl A.\(^{30}\) The selectivity of this material changes markedly with the concentration of the organic modifier used. At organic modifier concentrations below 50%, no interaction occurs between solutes and the stationary phase. Separation in such cases is governed by molecular sieving effects (Figure 8a). Increasing the concentration of the organic modifier above 55% causes retention of solutes to increase dramatically and bound solutes can subsequently be eluted with a decreasing gradient of \(n\)-propanol (Figure 8b). In an application aimed at identifying import components of the yeast mitochondrial membrane,\(^{31}\) the PolyHydroxyethyl A support was used to desalt proteins isolated by electroelution. Proteins obtained in such a way contain large amounts of SDS which interfere with subsequent analysis. To remove the detergent, electroeluted 45 kDa outer membrane protein was injected onto PolyHydroxyethyl A column equilibrated in 70% \(n\)-propanol. Testing the eluate for the presence of SDS with Fuchsir red showed that all of the detergent eluted with the injection front. Elution of the protein was achieved with an ‘inverse’ gradient. The 45 kDa outer membrane protein was eluted at the end of the gradient and was completely devoid of SDS (Figure 9). Other interfering low molecular contaminants from the electroelution process such as residual stain are also effectively removed. Spectral data obtained on a 30 kDa mitochondrial membrane protein after HILIC desalting showed no ultraviolet absorbing components above 280 nm which would indicate the presence of residual stain (Figure 10b). RPC of the electroeluate containing

![Figure 10 HILIC of an electroeluted 30 kDa membrane protein](image-url)

(a) An electroeluate containing approximately 5 µg of a 30 kDa mitochondrial membrane protein was applied with multiple 50 µl injections onto a PolyHydroxyethyl A column equilibrated in 70% \(n\)-propanol, 50 mM formic acid. After the baseline was stabilized, elution of the protein was started with a linear gradient from 70% \(n\)-propanol, 50 mM formic acid to 50 mM formic acid. The effluent was recorded at 280 nm. The inset shows the SDS polyacrylamide gel of the protein collected from the column. (b) RPLC of the desalted 30 kDa membrane protein. The protein pool from the PolyHydroxyethyl A column was diluted fivefold with 0.1% TFA and repeatedly injected onto a C4 Aquapore column (2.1 × 30 mm) and eluted with a linearly increasing gradient from 0.1% TFA to 75% acetonitrile, 0.1% TFA in 70 min at a flow rate of 150 µl min\(^{-1}\). Approximately 2 µg protein was injected. (c) The electroeluate containing an equal amount of the 30 kDa protein was injected onto the C4 Aquapore column without prior desalting by HILIC and eluted from the column under identical conditions. The insets show the absorption spectra of the peaks eluting at 57 min. The arrow marks the elution position of the 30 kDa protein.
the same 30 kDa membrane without HILIC desalting showed that the protein peak was totally obscured by the eluting Coomassie Blue stain (Figure 10c). However, it should be pointed out that, although HILIC and the inverse-gradient mode described by Simpson et al. are very effective in removing SDS from proteins, care should be taken when extremely hydrophobic proteins are chromatographed. The removal of SDS from proteins can lead to aggregation, especially when they are denatured. Whether organic phases such as acetonitrile or n-propanol are able to retain the protein in solution must be checked carefully in each application, otherwise severe protein losses can occur.

4 CONCLUSIONS

Hydrophilic interaction chromatography as introduced by Alpert is a versatile chromatographic tool which exploits hydrophilic interactions between solutes and a hydrophilic stationary phase. While RPHPLC is the most commonly used separation method for a variety of biological molecules, HILIC offers distinct advantages for the separation of specific mixtures of compounds. This is particularly true when HILIC is operated in the mixed-mode where separation is based on hydrophilicity/hydrophobicity differences combined with ion-exchange chromatography for the separation of solutes of varying net charge. For instance, separation of synthetic peptides from deletion impurities differing only slightly from the desired target sequence was achieved by HILIC/CEX, but not by RPHPLC. Furthermore, for resolving very complex mixtures, HILIC/CEX and RPHPLC can be ideally interfaced. Due to the high amount of organic modifier required for hydrophilic interactions, compounds resolved by RPHPLC in a first dimension are ideally suited for subsequent HILIC. One disadvantage of HILIC/CEX though, is that solutes are present at relatively high salt concentrations. The need to identify components is great, e.g. by coupling HPLC to MS. In such cases, gelfiltration on Polyhydroxyethyl A columns at low organic modifier efficiently separates salts from components down to a few hundred daltons. Alternatively, the use of volatile mobile phase additives for HILIC/CEX is currently under active investigation.

MALDIMS, first introduced in 1988 by Hillenkamp and Karas, has become a widespread analytical tool for peptides, proteins, and most other biomolecules (oligonucleotides, carbohydrates, natural products, and lipids). The efficient and directed energy transfer during a matrix-assisted laser-induced desorption event provides high ion yields of the intact analyte, and allows for the measurement of compounds with high accuracy and subpicomole sensitivity. This article discusses basic MALDI concepts and instrumentation and focuses on applications in the field of peptides and proteins, specifically on the utility of MALDI in protein identification, protein structural studies, and as a clinical assay.
analyte in both positive and negative ionization modes, respectively.\(^5\)

Several theories have been developed to explain desorption of large molecules by MALDI. The thermal-spike model\(^6\) proposes that the matrix molecules sublime from the surface as a result of local heating at low laser fluence, but above a certain laser intensity, a rapid rise in desorption efficiency is observed. The ejection of intact molecules is attributed to poor vibrational coupling between the matrix and analyte which leads to a bottleneck in the energy transfer from the matrix to the internal vibrational modes of the analyte molecule. The pressure pulse theory\(^7\) proposes that a pressure gradient is created normal to the surface and desorption of large molecules might be enhanced by momentum transfer from collisions with fast-moving matrix molecules.

It is generally thought that ionization occurs through proton transfer or cationization. The ionization depends critically on the matrix–analyte combination, but is not critically dependent on the number of acidic or basic groups of the analyte.\(^8\) This suggests that a more complex interaction of analyte and matrix, rather than simple acid–base chemistry, is responsible for ionization.

**1.2 Matrix-assisted Laser Desorption/Ionization Mass Analyzers**

There are three types of mass analyzers typically used with the MALDI ionization source: a linear time-of-flight (TOF), a TOF reflectron, and a Fourier transform mass analyzer (Figure 2). The linear TOF mass analyzer is the simplest of the three devices and has enjoyed a renaissance with the invention of MALDI. TOF analysis is based on accelerating a set of ions to a detector where all of the ions are given the same amount of energy. Because the ions have the same energy, yet a different mass, the ions reach the detector at different times. The smaller ions reach the detector first because of their greater velocity while the larger ions take longer owing to their larger mass. Hence, the analyzer is called TOF because the mass is determined from the ions’ time of flight. The arrival time at the detector is dependent upon the mass, charge, and kinetic energy (KE) of the ion. Since KE is equal to \(1/2 \cdot m \cdot v^2\) or velocity \(v = (2 \cdot KE/m)^{1/2}\), ions will travel a given distance, \(d\), within a time, \(t\), where \(t\) is dependent upon their mass-to-charge ratio \((m/z)\).

The TOF reflectron combines TOF technology with an electrostatic analyzer, the reflectron. The reflectron serves to increase the amount of time, \(t\), ions need to reach the detector while reducing their KE distribution, thereby reducing the temporal distribution \(\Delta t\). Since resolution is defined by the mass of a peak divided by the width of a peak or \(m/\Delta m\) (or \(t/\Delta t\) since \(m\) is related to \(t\)), increasing \(t\) and decreasing \(\Delta t\) results in higher resolution. This increased resolution, however, often comes at the expense of sensitivity and a relatively low mass range, typically <10000 m/z. One innovation that has had a dramatic effect on increasing the resolving power of MALDI/TOF instruments has been delayed extraction (DE). DE is a relatively simple means of cooling the ions (and possibly focusing them) immediately after the MALDI ionization event. In traditional MALDI instruments the ions were accelerated out of the ionization source as soon as they were formed; however, with DE the ions are allowed to “cool” for \(\sim 150\) ns before being accelerated to the analyzer (Figure 3). This cooling period generates a set of ions with a much lower KE distribution, ultimately reducing the temporal spread of ions once they enter the TOF analyzer. Overall, this results in increased resolution and accuracy. Incidentally, the benefits of DE significantly diminish with higher-molecular-weight proteins (>30000 Da).
Figure 3 DE versus continuous extraction.

MALDIMS is most commonly combined with the TOF mass analyzers. However, their somewhat limited resolution ($10^2$–$10^4$) results in accuracy on the order of 0.2% to a high of 0.005% (with internal calibrant). Alternatively, MALDI instruments are also being coupled to ultrahigh-resolution ($>10^7$) mass analyzers such as the Fourier transform ion cyclotron resonance (ICR) mass analyzer. First introduced in 1974 by Comisarow and Marshall, Fourier transform mass spectrometry (FTMS) is based on the principle of a charged particle orbiting in the presence of a magnetic field. While the ions are orbiting, a radio frequency (RF) signal is used to excite them and as a result of this RF excitation, the ions produce a detectable image current. The time-dependent image current can then be Fourier-transformed to obtain the component frequencies of the different ions which correspond to their $m/z$. FTMS has become an important research tool offering high accuracy with errors as low as ±0.001% (ppm accuracy). Different types of MALDI mass analyzers are compared in Table 1.

MS, mass spectrometry.
example, a protein can often be unambiguously identified by the accurate mass analysis of its constituent peptides (produced by either chemical or enzymatic treatment of the sample). Furthermore, protein identification can also be facilitated by analysis of the protein’s proteolytic peptide fragments in the gas phase; fragment ions generated inside MALDI mass spectrometers via collision-induced dissociation (CID) yield information about the primary structure and modifications. Tandem mass spectrometry (nMS) experiments, previously allowed with quadrupole and ion trap mass spectrometers are now attainable with MALDI sources (known as postsource decay or PSD).

While the MALDI mass spectrometer is a powerful tool for the accurate mass determination of peptide mixtures, obtaining accurate mass measurements is highly dependent upon the sample and the sample preparation. Acquiring optimum MALDI data depends on the choice of suitable matrices and solvents, the functional and structural properties of the analyte, sample purity, and how the sample is prepared on the MALDI sample plate. Because the solvent or matrix is the medium by which the analyte will be transported to the gas phase and provides the conditions that make ionization possible, contamination of the sample with excessive salt (>10 mM) will affect these conditions and lead to reduced sensitivity. This is also true of chaotropic agents, including urea and guanidinium salts, and solvents like dimethyl sulfoxide and glycerol. Dialysis and reversed-phase liquid chromatography (RPLC), or exchange chromatography are useful methods for purifying samples of such contaminants prior to mass spectral analysis.

2.1 Sample Preparation

For peptides and proteins, the standard matrices (10–13) are α-cyano-4-hydroxycinnamic acid (1) (α-cyano or CCA), 3,5-dimethoxy-4-hydroxycinnamic acid (2) (sinapinic acid or SA), and 2,5-dihydroxybenzoic acid (3) (DHB). CCA (1) is mainly used for peptides, glycopeptides and small proteins. SA (2) is commonly used for both peptide and protein analysis, and DHB (3) is used for glycopeptides, glycoproteins, small proteins, and oligonucleotides (<10 bases). In the analysis of protein digests (peptide mapping), the choice of matrix plays an important role in the observation of the peptides produced. Some matrices can complement each other with respect to obtaining complete protein sequence coverage, for instance peptide mapping with CCA can yield more low-mass peptide ions (<2500 Da), while SA may provide better coverage for the higher-mass peptides (>2500 Da).

Sample–matrix preparation procedures greatly influence the quality of MALDI mass spectra of peptides/proteins. Among the variety of reported preparation methods, the dried-droplet method is the most frequently used. In this case, a saturated matrix solution is mixed with the analyte solution, giving a matrix-to-sample ratio of about 5000:1. An aliquot (0.5–2.0 µL) of this mixture is then applied to the sample target where it is allowed to dry. Below is one specific example of the dried-droplet method:

- Pipet 0.5 µL of sample to the sample plate (preferable concentration ~ 1.0 pmol µL⁻¹).
- Pipet 0.5 µL of matrix to the sample plate.
- Mix the sample and matrix by drawing in and out of the pipette.
- Allow to air dry.
- For peptides, small proteins, and most compounds a saturated solution of CCA (1) in 50:50 H₂O:acetonitrile (ACN) with 0.1% TFA (trifluoroacetic acid) is used.
- For glycopeptides/proteins and small compounds a saturated solution of DHB (3) in 50:50 H₂O:ACN with 0.1% TFA is used.
- For proteins and other large molecules a saturated solution of SA (2) in 50:50 H₂O:ACN with 0.1% TFA is used.

Alternatively, samples can be prepared in a stepwise manner. In the thin-layer method, (14,15) a matrix homogeneous “film” is formed on the target first, and the sample is then applied and absorbed by the matrix. This method yields good sensitivity, resolving power, and mass accuracy. Similarly, in the thick-layer method, (16) nitrocellulose (NC) is used as matrix additive and once a uniform NC-matrix layer is obtained on the target, the sample is applied. This preparation method suppresses alkali adduct formation and significantly increases the detection sensitivity, especially for peptides and proteins extracted from gels. The sandwich method (16) is another variant in this category. A thin layer of matrix crystals is prepared as in the thin-layer method, followed by the subsequent addition of droplets of aqueous TFA, sample and matrix.
2.2 Protein Primary Sequence Analysis

Amino acid sequence information can be obtained by one of several methods using MALDIMS. The first is called protein mass mapping which consists of the site-specific enzymatic or chemical degradation of a protein followed by mass spectrometric analysis of the released peptides. Owing to the complexity of mixtures generated during proteolysis, MALDI/TOF MS is most ideally suited for such analyses. The traditional analytical methods used to characterize the released peptides consist of high-performance liquid chromatography (HPLC) or gel electrophoresis followed by N-terminal (Edman) sequencing and/or amino acid analysis. However, such methods are considerably more time-consuming and in some cases are not capable of separating individual peptides because of their low resolution. Consequently, high-resolution MALDI/TOF analysis can provide for a more rapid, accurate, and highly sensitive analysis of these complex peptide mixtures.

The purpose of protein mass mapping is not to sequence the entire protein but instead to generate information that can be used in protein database searches either to identify the protein or determine whether the protein is novel. Protein identification via database searching is facilitated by the accurate $m/z$ values of the digest fragments, the specificity of the enzyme used, and the accurate $m/z$ of the intact protein. Entire scientific conferences have been devoted to this approach which has been coined “proteomics.” Table 2 previews some of the protein databases available on the internet.

by use of pulsed lasers to photodissociate selected ions. Other advantages associated with using FTMS include the simultaneous high mass resolving power of the fragments, the high sensitivity over a wide mass range and the high mass accuracy. The primary disadvantage is the lack of multiply charged species generated in MALDI/FTMS experiments, the lack of which reduces the amount of fragmentation. Figure 6 shows the MALDI/FTMS MS/MS spectrum of a viral peptide obtained from a mutant common cold (rhino) virus. Such analysis provided for the rapid (<20 min) identification of the mutated amino acid with <5 ppm mass accuracy.

2.3 Characterizing Protein Modifications (Co- and Posttranslational)

Protein modifications, including both co- and posttranslational modifications (e.g. phosphorylation, sulfation, glycosylation, and N-terminal modifications), are recognized as important means of regulating the cellular distribution and modulating protein functions. For example, protein phosphorylation is known to play a critical role in cell signal transduction pathways. Carbohydrates provide various functional, immunological, and structural aspects of glycoprotein. Characterization of protein modifications is an important aspect for analyzing protein structure and function. The utility of MALDI for this purpose relies on its ability to perform accurate mass determination of peptide mixtures, its very high sensitivity and resolving power, and its buffer tolerance.

Typical MALDI protocols for protein modification characterization begin with the enzymatic digestion of the protein sample, resulting in a complex mixture of peptides. When a protein’s primary structure is known, the molecular weight of a peptide can be used to corroborate the presence of any modification by its specific molecular-weight difference between the observed mass of peptide and that calculated on the basis of the sequence. This approach is straightforward but has very little specificity and selectivity. The results can be ambiguous if a complicated digestion mixture is presented. This difficulty can be overcome by using MALDI PSD MS/MS to generate and record metastable fragment ions. The aid of a separation technique, usually HPLC, is sometimes needed before the MALDI analysis. This protein modification characterization approach has been employed by several groups to identify and sequence either glycoproteins or phosphoprotein.

2.4 Protein Structure Elucidation

Proteins in their native state are typically folded into well-defined, three-dimensional structures by relatively weak intramolecular forces (i.e. hydrogen bonds, electrostatic, or hydrophobic interactions). Because the function of the protein relies heavily on this structure, information on higher-order structure (i.e. tertiary protein conformation and quaternary protein–protein interactions) is of fundamental biological importance. There are a variety of spectroscopic methods available to study tertiary and quaternary protein structure, including X-ray crystallography and nuclear magnetic resonance (NMR), along with a variety of other spectroscopic techniques. It should be noted, however, that while these techniques constitute the state of the art as far as structural determination, they can be time-consuming and require deconvolution of complex data and a significant amount of material.

An alternative approach to investigate higher-order protein structure using MS is to probe the surface availability of regions of the molecule using the protein mass mapping method. Proteolytic digestion is dependent on the availability of cleavage sites which is a reflection of the protein structure. Therefore, proteolysis performed in modified solution conditions can sample different protein conformations, and relative differences in these conformations can then be discerned through direct comparison of the resulting mass spectrometric data. For example, digestion of a protein in its denatured or unfolded state will most likely result in the release of additional digest fragments when compared to the digest of the protein in its native or folded state. In the unfolded state, more cleavage sites will be accessible to the protease owing to lack of tertiary structure.

Using this method, Lewis was able to recognize conformational differences (i.e. changes in tertiary structure) in regulatory proteins brought on by the interaction with an effector molecule. The allosteric protein calmodulin (CaM) is known to take on different conformational states depending on the presence or absence of its effector, calcium. Different proteolytic mass maps were observed for CaM, indicating structural differences in the protein depending on the presence of calcium.

The overall tertiary structure of CaM reveals a dumbbell shaped molecule (148 amino acids) with two
globular domains separated by a single long central \( \alpha \)-helix (amino acids 65–92). It has been proposed that calcium activates CaM by exposing hydrophobic residues (near the two ends of the central helix) which interact with CaM target proteins. Small-angle X-ray scattering analysis has shown that the central helix acts as a flexible “tether” which, upon binding calcium, allows the two globular domains to come together and in effect “hug” the target protein, via the hydrophobic regions. Mass maps resulting from digests by trypsin, chymotrypsin, and pepsin all indicated that the protein had undergone a tertiary structural change in the presence of calcium and in doing so hindered the activity of the enzyme in the central helical region. Presumably, the coming together of the two globular domains places certain residues of the central helix, normally cleaved in a calcium-free environment, in a conformation which does not allow the enzyme accessibility.

Thus, in observing qualitative differences between spectra obtained in the absence and in the presence of an effector, the mass mapping approach allows different solution conformations (differences in tertiary structure) of a protein to be identified and which regions of a protein are effected by such conformational changes to be determined. Figure 7 shows the trypsin digests of CaM in the presence and absence of calcium. Comparison of the two mass spectra reveals obvious qualitative differences corresponding to cleavages in the central helical region of the protein. Digestion fragments resulting from cleavages in the central region (residues 65–92) of the molecule are not present in the calcium-free environment.

Investigating protein/protein interactions (quaternary protein structure) has also been pursued with limited proteolysis combined with MS, the goal being to determine the topographical regions involved in their interaction. Again, since enzymatic digestion of a protein is dependent on the availability of cleavage sites, it can be assumed that digestion of a protein complex should hinder access of the protease to cleavage sites normally accessible in the digestion of the individual proteins. Toward this end, comparative mass mapping should reveal regions of the protein(s) involved in the formation of the complex. Changes in the susceptibility of cleavage sites toward proteases can arise from several physical effects as a result of the complex formation. One is a direct consequence of the formation of the complex, the steric hindrance, and another is an indirect result of the formation of the complex, a conformational change, that may alter the accessibility of not only

the sites involved in the interaction, but remote sites as well.

Siuzdak et al. performed MALDI analysis on the digests of the kinase inhibitory domain of the cell cycle regulatory protein, p21-B in both the free solution state and in the 1:1 complex of p21-B and cyclin-dependent kinase 2 (Cdk2) as shown in Figure 8. Mass mapping of the trypsin digests of the free p21-B revealed peaks corresponding to all of the 12 potential trypsin cleavage sites (amino acids 9, 16, 19, 20, 32, 46, 48, 67, 69, 75, 83, and 84). However, MALDI mass spectra for the trypsin digests of p21-B in the presence of Cdk2 showed that several p21-B fragments that were produced in the absence of Cdk2 disappear in the presence of Cdk2. Specifically, Siuzdak et al. found that amino acids 46, 48, 67 were protected from trypsin cleavage in the presence of Cdk2. This data was later crystallographically supported by the crystal structure data on a homologous system using a p21 homolog p27.

Other methods of probing higher-order structure include investigating the chemical reactivity of individual amino acids in a protein and chemical cross-linking studies. Both approaches stem from the fact that MALDI has proved to be a powerful method with which to characterize covalent post-translational modifications. Using simple modification chemistries such as acylation or succinylation, Glocker et al. have shown that there is a clear correlation between the relative reactivity of specific amino acids and their surface (accessibility) topology in a protein. Chemical cross-linking studies consist of treating proteins with cross-linkers prior to digestion. Cross-linkers covalently attach adjacent protein regions or protein subunits, therefore the resulting proteolytic fragments are good indications of the overall tertiary and/or quaternary protein structure.

3 APPLICATIONS

3.1 Diagnostic

As mentioned previously, the power of MALDI lies in its ability to analyze complex mixtures, making MALDI a promising method for the diagnostic screening of biological fluids (serum, cerebrospinal fluid, urine). However, low analyte concentrations and signal suppression due to large amounts of host protein (e.g. hemoglobin in blood) often hinder the screening of such complex mixtures. The MSIA method improves sensitivity, allowing for the detection of smaller concentrations of analytes.

![Figure 9](image_url)
It therefore becomes necessary to isolate the analyte from the fluids prior to MALDI analysis. Mass spectrometric immunoassay (MSIA) (Figure 9), developed by Nelson et al., relies on the affinity capture (antibody–antigen recognition) of the analyte from the biological matrix prior to mass spectrometric analysis. This method not only preconcentrates the analyte, but also provides for the most selective form of analyte isolation, making this an extremely powerful technique for screening biological fluids. Nelson et al., for example, were able to detect unambiguously femtomole amounts (nanomolar concentrations) of a snake toxin doped into human whole blood.

Similar to the enzyme-linked immunosorbent assay (ELISA), MSIA consists of the nanoscale immunoaffinity purification of the analyte of interest. Isolation is performed by incubating the biological matrix with antibodies immobilized on a solid support, such as resin beads. During incubation, the analyte is captured on the immobilized antibody and, after a series of washes, the antibody–antigen interaction is disrupted by the addition of the acidic MALDI matrix. Subsequent mass spectrometric analysis of the eluant confirms the presence of the antigen (analyte) at a specific \( m/z \) value. Unlike the ELISA, however, any nonspecifically bound molecules can be unambiguously differentiated from the analyte of interest owing to unique \( m/z \) values measured. In addition, incubation times are on the order of 15–20 min, significantly shorter than with the conventional ELISA.

In preliminary experiments aimed at identifying cardiac troponin T (cTnT) present in the urine of chronic renal failure patients, Fitzgerald et al. used biotinylated-anti-troponin mAb immobilized on streptavidin beads to affinity capture 0.15 \( \mu \)g mL\(^{-1}\) (\( \sim \)44 pmol) cTnT from Tris buffer. In the MALDI mass spectrum of 9 \( \mu \)g mL\(^{-1}\) cTnT in 100-mM Tris buffer (Figure 10b), no ion signals of cTnT are observed. Figure 10(a) shows the mass spectrum obtained after the MSIA isolation and elution, where cTnT is observed at \( m/z \sim 34 \) kDa. Thus, the combination of MS with immunoaffinity capture serves as a rapid, sensitive, and selective means of detecting biologically relevant compounds.

### 3.2 Quantitative Aspects of Matrix-assisted Laser Desorption/Ionization

The ability of MALDI to analyze complex heterogeneous mixtures has made it a common and valuable technique in the analysis of biological fluids, analysis commonly performed by immunoassays and HPLC. Immunoassays generally have low reproducibility and reliability and provide little or no selectivity between a drug and its metabolites. This lack of specificity is a significant limitation since metabolites, although structurally similar to the parent compound, often have different biological activity. Mass spectrometric analysis, on the other hand, allows for co-extracted metabolites to be identified and quantitatively monitored (unless they have the same molecular weight). Although HPLC is relatively selective and accurate, the sensitivity is compound dependent and method development can be time-consuming. Thus, while both techniques are useful, both suffer when compared to the speed, sensitivity, and accuracy offered by MS.

In the following example, an automated MALDI MS procedure was used to improve the clinical analysis of a cyclic peptide (the immunosuppressant drug cyclosporin A (CsA)) (4) from whole blood extracts. A MALDI mass spectrometer equipped with automated multisampling capabilities was used to facilitate data collection and analysis of CsA. Extraction optimization was performed by generating an array of solvent systems to identify successful extractions. The first generation of experiments revealed four effective binary solvent systems (hexane/EtOH, ACN/H\(_2\)O, ACN/MeOH, hexane/CHCl\(_3\)). A new array based on these solvent systems was generated and in a second iteration of these experiments, hexane/CHCl\(_3\) (70:30) was found to provide the most effective single-step extraction for cyclosporin and its metabolites (Figure 11). In order to determine the efficiency of the new extraction
MALDI MASS SPECTROMETRY IN PEPTIDE AND PROTEIN ANALYSIS

procedure it was compared to the previously developed “ether” extraction.

Initially, calibration curves were obtained using the “ether” extraction (a plot of the ratio of \( \text{int}[\text{CsAH}^+ + \text{CsANa}^+] / [\text{CsGH}^+ + \text{CsGNa}^+] \) vs CsA concentration) with both the ESI (electrospray ionization) and MALDI mass spectrometers (cyclosporin G, CsG, was used as the internal standard). The data exhibited a linear relationship in the concentration range 0–1500 ng mL\(^{-1}\) (Table 3) with an excellent correlation coefficient (\( R^2 = 0.999 \)) for both electrospray and MALDI. The new extraction generated standard curves for CsA that were very similar to those from the “ether” extraction method.

Table 3 Results obtained from the ESI/MS and MALDIMS analysis of extracted SA from standard blood samples using the 70/30 hexane/CHCl\(_3\) extraction

The automation of MALDI analyses, such as that used in the cyclosporin study, is becoming increasingly important in proteomics and combinatorial chemistry. These analyses are driven by a computer-controlled procedure to monitor the ion signal as a function of laser position and laser intensity (Figure 12). To accomplish this, the computer workstation automatically adjusts laser intensity and searches the sample well until a signal (within the specified mass range and intensity threshold) is obtained. Based on a careful preselection of autosampler options, each parameter (laser intensity, search pattern and step size in well, signal within a specified \( m/z \) range, and \( m/z \) range) is adjusted to minimize time of analysis and maximize signal quality.

What follows is a brief description of a MALDI automation procedure performed for the analysis of peptides. Here, the laser intensity was initially set at a minimum energy setting and then allowed to increase up to a maximum (~2–50 µJ/pulse, as controlled by a variable neutral density filter). Step sizes were made in five increments, resulting in an increase in laser intensity of approximately 10 µJ/pulse per step. The laser intensity was increased until an acceptable data signal was acquired, whereby if no signal was observed the laser beam was repositioned on the well and MALDI analysis resumed at the lower laser power. To adjust the laser position on the MALDI sample plate, a preprogrammed spiral search pattern was used which began in the center of each circular well and spiraled outward in 0.2 mm increments. For each sample well analysis, only signals that reached a specified intensity were saved and once this signal was observed the analyses would automatically move to the next well. On average the total time spent for each sample well analysis was 140 s. This included acquisition time for averaging 64 scans and a delay for adjusting laser intensity and repositioning the sample plate.
3.3 Characterizing Peptides and Reactions Directly from the Solid Phase

Several reports have shown that MS can be very useful in characterizing compounds covalently bound to solid polymeric supports subsequent to their chemical cleavage from the resin. More specifically, the characterization of peptides and carbohydrates covalently linked to a polymeric support through a photolabile linker is feasible using MALDIMS. The scheme outlined in Figure 13(a) permits the characterization of resin-bound analytes in a single step and requires no pretreatment of the sample to induce cleavage from the support. In addition, this approach also shows that the technique is suitable for monitoring chemical reactions on the solid phase.\(^\text{(33,34)}\)

Figure 13(b) shows the mass spectrum of the unprotected resin-bound peptide. MALDI analysis yielded a characteristic \([M+H]^+\) signal at \(m/z\ 1247\) which is consistent with the expected mass of the free peptide (MW = 1245.5 Da). The spectrum in Figure 13(b) was acquired from a single bead. The peptide (in a chemical cleavage step) was recovered from resin samples and then subjected to MALDI analysis, indicating that the sample was not completely photolyzed in the experiment. This is not surprising, as only a small amount of material (<femtomoles) is typically consumed during such analysis. Figure 13(c) shows the MALDI analysis of resin-bound carbohydrate, illustrating the application of this technique to another class of compounds.

The one-step MALDI procedure for the direct analysis of resin-bound molecules described above is also well suited to studying chemical reactions on the solid phase. As a demonstration of this utility, the coupling reaction of a Boc-Arg(Tos) residue (preactivated as the hydroxybenzotriazole ester) to the protected 11 amino acid peptide (described above) was monitored as a function of time. Interestingly, the Fmoc protected peptide was not amenable to MALDI analysis; the absence of appropriate protonation sites in this sample probably prevents ionization. Therefore, prior to analysis resin samples were treated with 20% (v/v) piperidine in dimethylformamide (DMF) in order to remove the Fmoc protecting groups, after which the reaction proceeded quickly and coupling appeared nearly complete in just 6 min.

The direct analysis of resin-bound molecules by MALDI offers several important advantages. The first is the lack of an additional cleavage step prior to mass analysis, which is often required by other methods of characterization. Performing MALDI directly on the solid phase requires less sample handling and more efficient management since the resin-bound compound can be easily recovered for subsequent manipulations (again, <femtomoles of material is consumed in typical MALDI analyses). The most significant advantage is that it can be used to monitor chemical reactions on the solid phase in real time, in much the same way that thin-layer chromatography is used to monitor reactions in solution. Furthermore, all analytes amenable to MALDI ionization should prove suitable for routine analysis by this procedure.

4 CONCLUSION

Since the late 1970s, tremendous progress has been made in the analysis of peptides and proteins by MS. Much of this enormous growth can be attributed to advances in desorption/ionization techniques such as MALDI, namely in resolution and accuracy. In addition, it is now routine to analyze peptides and proteins at femtomole levels which makes it well suited for protein mass mapping and structural determination. We are all familiar with the prominence of gel electrophoresis methods in molecular biology studies; we posit that MS methods will capture this position as a primary research tool in coming years owing to its superior sensitivity, precision, accuracy, and throughput. The applications discussed here are just a few examples of current approaches that will see expanded use in the future.

This article describes the theoretical background and practical applications of classical molecular mechanics and molecular dynamics (MD). Following a brief historical outline of molecular modeling, the concept of the molecular potential energy function is introduced and the basic algorithms of molecular mechanics: energy minimization, normal mode analysis, MD and Monte Carlo (MC) simulations are defined. The advantages of molecular modeling methods – speed of calculations and detailed microscopic insight – are described. The shortcomings – approximate nature and difficulties with conformational sampling – are also analyzed. A number of modern approaches aimed at improving the reliability of computer simulations are briefly presented, including advanced energy optimization methods, treatment of long-range forces and accelerated conformational exploration. Examples of applications of molecular modeling methods to study of various aspects of structure, dynamics and function of peptides and proteins are presented. A brief exposition of the relationship between molecular modeling and some fundamental experimental techniques, such as X-ray crystallography, neutron scattering, nuclear magnetic resonance (NMR), fluorescence and vibrational spectroscopies is provided. Finally, an outline of future directions of modeling studies is suggested.

1 INTRODUCTION

The term “molecular modeling” covers a wide range of approaches used to calculate, analyze and visualize molecular properties. The spectrum of methods ranges from physical models, made of plastic or wire, to structural rendering by computer graphics and mathematical models of different levels of sophistication. This article focuses on the theoretical background and practical applications of classical molecular mechanics and MD, a mathematical model widely used in computational studies of physical, chemical and biological properties of molecular systems. The wider field of molecular modeling, including protein homology modeling, docking studies, extended atom and lattice models, electrostatic PB (Poisson–Boltzmann) methods and quantum chemical calculations will be only briefly mentioned.

In molecular mechanics, the fundamental quantity is the potential energy function, which enables assignment of energy values to the different configurations of the atoms comprising the system. The availability of the energy as a function of atomic positions allows the relative stability of different structures (conformational search) to be determined. First derivatives of the potential with respect to atomic coordinates yield the forces acting on the atoms. The forces may be used to numerically solve equations of motion of the molecular system (MD) or to locate energy minima (energy minimization or structure optimization). Second derivatives of the potential energy yield the harmonic force constants, which are the basis for normal mode analysis and predictions of vibrational spectra and collective modes of motion.

Using basic principles of physics and chemistry, computer simulations employing the model molecular mechanics potential may be used to predict a wide range
of properties for molecular systems. These properties include the stable structure (or group of structures), intermolecular interactions, types of motion present and their timescales. These general quantities can be related to specific observables – structures, dipole moments, diffusion coefficients, vibrational spectra, NMR spectral parameters, etc. Using specialized simulation techniques, free energy differences between various molecular states may be evaluated, allowing calculations of such quantities as population ratios of peptide conformers or binding constants for protein-inhibitor complexes.

Molecular mechanics models have two main advantages – speed and interpretive power. Standard molecular mechanics calculations use simple potential energy functions, which can be rapidly evaluated for large molecular systems – such as solvated peptides or proteins, including 10,000 or more atoms. At this time such large systems cannot be extensively studied by the (in principle) more accurate quantum mechanical approaches. By considering motions of individual atoms over timescales starting in the sub-picosecond range, simulations provide an enormous amount of microscopic detail about molecular structure and dynamics. Once the reliability of the simulation protocol has been verified by comparison with available experimental data, the detailed atomic-level predictions may be used to provide valuable insight into the microscopic mechanisms of observed phenomena. Such insight is highly valuable in developing basic understanding of complex molecular systems, guiding the development of new experiments and manipulation of molecular properties for practical purposes.

The main limitations of classical molecular mechanics lie in the approximate nature of the potential energy functions and in the difficulty of sampling the conformational space of large, flexible molecules such as peptides or proteins. In order to make the calculations fast and applicable to a wide range of systems, a number of simplifying assumptions about the form of the potential are usually made, such as the harmonic and diagonal form of the internal deformation force field, use of fixed point charges to describe electrostatic interactions, pair-wise additivity of atom–atom nonbonded interactions and truncation of long-range forces. These approximations limit the accuracy of the calculated energies. Further, the classical potentials refer to a fixed electronic state, so that processes involving chemical reactions cannot be modeled using the standard molecular mechanics approach. The problem of potential accuracy and modeling of chemical reactions may in principle be overcome by using the more expensive quantum mechanical methods. The conformational sampling problem is even more difficult, as there is currently no viable approach for solving it. This problem is due to the fact that the number of possible states of a molecular system grows exponentially with the number of atoms. As a consequence, it is currently impossible to exhaustively explore the conformational space of large flexible molecules. Thus, molecular mechanics cannot predict the three-dimensional structure of a small protein with 100 amino acid residues from first principles. Using explicit molecular solvent models, even structure prediction of a decapeptide in solution is beyond the range of current methods. For large molecular systems we have to employ experimental information on structure and use special simulation techniques to obtain reliable results.

In spite of its limitations, and thanks to its speed and insights, the molecular mechanics approach is being extensively used in studying peptides, proteins and other complex systems. Due to continuing improvements in potentials, simulation algorithms and computer power, more reliable results are being obtained for ever larger systems. As the number of successful applications grows, the computer simulations based on molecular mechanics methods are becoming widely accepted as a useful tool in the arsenal of modern chemists and biologists, a tool complementary to both experimental and theoretical approaches.

2 HISTORY

The development of quantum mechanics in the 1920s and 1930s led to the concept of the molecular potential energy surface, expressing the energy as a function of positions of nuclei. Attempts to model molecular properties using simple potentials soon followed. Interpretation of molecular vibrational spectra in terms of normal modes and the underlying harmonic force constants of small symmetric molecules developed during the 1930s and 1940s. An early study involving molecular motion is the 1936 classical trajectory calculation for the H + H2 $\rightarrow$ H2 + H reaction. Quantitative description of molecular strain in simple organic molecules through harmonic bond stretching and angle deformations, and Lennard–Jones interactions or exponential repulsion between nonbonded groups was proposed in 1946 by Hill and Westheimer and Mayer. An internal rotation barrier of the form $V_0[1 – \cos(3\phi)]$ for methyl groups was employed to explain the entropy of ethane in 1936. Potentials including electrostatic interactions between atomic partial charges were used by Kitaigorodskij in the 1950s to investigate the properties of organic crystals. A simple hard-sphere model was employed to predict the allowed conformations of amino acids in 1963. An interesting account of the early history of molecular modeling is given by Rappe and Casewit.
Potentials for modeling wider classes of polyatomic molecules, including peptides and proteins, became available in the 1960s, 1970s and 1980s. This period coincided with the introduction of computers and computer-based numerical calculations into chemistry, physics and biology. The basic tools of molecular modeling – energy minimization, normal mode analysis, MD and MC simulations were also developed in those years.

Simulations started with simple systems – hard-sphere fluids, liquid argon with a Lennard–Jones potential and pure water. Studies of other liquids and solutions followed. The first MD simulation of a small protein, a 9 ps trajectory of bovine pancreatic trypsin inhibitor (BPTI) in vacuum, was reported in 1977. Further MD and normal mode studies of proteins in vacuum followed in the 1980s: myoglobin, lysozyme, BPTI, crambin, ribonuclease. Molecular free energy simulations were introduced in the late 1970s and early 1980s, first for simple model systems and then for point mutations in proteins. Attempts to include electric polarization were introduced. Methods to efficiently and accurately model chemical reactions in condensed phases based on the valence bond and quantum mechanics/molecular mechanics (QM/MM) approach were implemented. Finally, further increases in computer power and algorithm development in the 1990s brought studies of solvated peptides and proteins, inclusion of long-range interactions, explicit treatment of mobile counterions, simulations of protein folding/unfolding events, efficient path exploration, multiple time stepping (MTS), and advanced conformational search strategies.

4 OVERVIEW OF MODELING METHODS

The molecular mechanics approach to molecular modeling starts with the definition of the potential energy function. The potential is crucial for the basic simulation algorithms – energy minimization, normal mode analysis, MD and MC methods. These algorithms may be applied to explore various properties of the modeled systems – from favored conformations to structural fluctuations, detailed microscopic dynamics and free energies of conformational transitions or mutation processes. In the course of the modeling, special attention needs to be paid to the complexity of the energy landscape, treatment of solvation, long-range interactions and large-scale structural change.

4.1 Potential Energy Functions

At the fundamental level a molecular potential energy function $U$ may be identified with the total energy of a system of electrons and nuclei in the Born–Oppenheimer approximation of quantum mechanics. From the quantum mechanical viewpoint $U$ consists of the kinetic energy of the electrons and three Coulombic terms, describing electron–electron, electron–nuclear and nuclear–nuclear interactions, all in a given electronic state. Thus, in the classical description the potential depends only on positions of nuclei (or atoms). To facilitate calculations and relate the energy to chemical structure, the form of $U$ is usually parameterized in terms of simple structural descriptors – bond lengths, bond angles, dihedral angles and nonbonded atom–atom distances. A typical form of the potential, shared by many publicly available force fields, such as CHARMM, AMBER, OPLS, or GROMOS is shown in Equation (1):

$$U = \frac{1}{2} \sum_{\text{bonds}} k_b (b - b_0)^2 + \ldots + \frac{1}{2} \sum_{\text{angles}} k_\theta (\theta - \theta_0)^2 + \frac{1}{2} \sum_{\text{impropers}} k_w (w - w_0)^2 + \frac{1}{2} \sum_{\text{dihedrals}} k_\phi + \sum_{\text{atom pair } \bar{ij}} \left( \frac{q_i q_j}{R_{ij}} - \frac{A_{ij}}{R_{ij}^6} + \frac{B_{ij}}{R_{ij}^{12}} \right)$$

(1)

3 PEPTIDE AND PROTEIN STRUCTURE

Peptides and proteins are polymeric chains built from 20 commonly occurring amino acids. The primary structural coordinates are the flexible backbone dihedrals $\phi$ and $\psi$, and sidechain dihedrals $\chi_1, \chi_2, \ldots$ (Figure 1). Proteins and many peptides exhibit a tendency to exist in a single, well defined three-dimensional structure, denoted as the folded form. The folded structures are characterized by the presence of secondary structure elements – mainly $\alpha$-helices, $\beta$-sheets and several kinds of regular turns. In proteins, the secondary structure elements are further organized into structural motifs. Several examples are shown in Figure 1. Further complexity is added by the presence of noncovalent cofactors such as porphyrins, nucleotides or metal ions, the possibility of forming covalent disulfide bonds between Cys sidechains, and aggregation of individual subunits to form quaternary structure. In principle, the properties of a peptide/protein system are determined by the sequence. However, in practice the complex problem of predicting protein structure, dynamics and function from the sequence alone is at present intractable. A summary of the difficulties encountered and solutions proposed to this challenging problem is presented below.
In this equation, \( b, \theta, w, \phi \) and \( R_{ij} \) are the actual bond lengths, valence bond angles, improper and proper dihedral angles and atom–atom distances for a given configuration of the system, respectively; \( k_b, b_0, k_\theta, \theta_0, k_w, w_0, k_\phi, n, \delta, q_i, A_{ij} \) and \( B_{ij} \) are parameters. One way of looking at potential energy functions of this type is to treat them simply as mathematical models leading to certain predictions. However, both the method of derivation and the form of the function gives the parameters physical meaning.

The first three terms in \( U \) describe energies of deformation from equilibrium of chemical bond length \( (b) \), bond angles \( (\theta) \) and improper dihedrals \( (w) \). These distortions are usually small under normal conditions, allowing the energy to be described in the form of a sum of harmonic (Hooke’s law) terms. The presence of these terms assures that throughout the simulation the molecule preserves its basic chemical structure.

The fourth term in \( U \) above describes the energy of torsion around chemical bonds—it is periodic and is modeled as a cosine term (or sum of several cosines with different periodicities). The presence of the \( \cos(n\phi) \) term assures that the molecule will sample \( n \) distinct potential energy minima as the complete rotation around
the chemical bond is performed. Taken together, the first four terms might be considered as the strain energy of deforming a molecular structure from equilibrium. For further discussion about the approximations involved in the first four terms see section 4.4.

The last term of the formula for $U$ describes the nonbonded interactions between pairs of atoms, and has two contributions: electrostatic interactions between point charges (usually located at atom centers) and a Lennard–Jones 6–12 potential which models the universal features of interatomic interactions: weak attraction at moderate distances and strong repulsion on close contact. For a review of theoretical and experimental aspects of intermolecular interactions see Margenau and Kestner[53] and Israelachvili.[54] The internal strain is the dominant factor in determination of the structure of small, relatively rigid molecules such as water or benzene. In larger, flexible molecules such as peptides and proteins, the torsional deformations and nonbonded interactions play a major role.

There are several approaches to determine the potential parameters.[8] Most force fields, e.g. AMBER, CHARMM, GROMOS, OPLS, MM2, MM3,[55] and Tripos, primarily aim to reproduce experimental data, such as molecular geometries, vibrational frequencies, torsional barriers, conformational energy differences, heats of vaporization or sublimation, densities, etc. Due to paucity of accurate experimental measurements, increase in computer power and proliferation of quantum chemistry codes, the use of electronic structure calculations is gaining popularity as a source of data. The mostly empirical force fields listed above usually use some quantum chemical information, e.g. to calculate atomic point charges or vibrational frequencies. The Discover force field is an example of a potential parameterized mainly on quantum calculations, with some empirical corrections.[56] In both the quantum and empirical approaches, some parameters may be determined directly (e.g. bond lengths), while others are optimized by indirect fitting to data (e.g. force constants derived from vibrational spectra, van der Waals radii from heats of vaporization). Generally, parameter values are determined in studies of small molecular models such as amino acids or their fragments in condensed phases – crystals or liquids. The assumption that the same parameters may be used to describe macromolecules is verified by comparison of calculated and observed properties. The above force fields provide relatively accurate models for classes of molecules that have been used in the parameterization. The price of this accuracy is that extension of the models to new types of molecules typically requires some rather time-consuming parameter development. An alternative to this approach is provided by force fields such as DREIDING[57] or UFF (universal force field[58]) which assign most parameters based on simple general rules. In the rule-based methods, the loss of accuracy is offset by the more general applicability of the models.[8]

Even the relatively simple formula in Equation (1) is not evaluated directly as is, and further approximations are usually made in nonbonded energy evaluation. For a system of $N$ atoms there are $N(N-1)/2$ distinct pair interactions; e.g. with $N = 10 000$ we get almost 50 million pairs. Calculating all these terms would take too much computer time, especially in MD or MC simulations, which typically require millions of energy evaluations. To increase the speed of computation, the nonbonded terms for atoms separated by more than a specified cutoff distance are ignored. The cutoff distances used in different force fields tend to increase with time, as computer power grows. Typical cutoffs used in the 1990s were 9–12 Å.[49] In order to remove any discontinuities in the energy or its derivatives due to the cutoff, the calculated energies had to be further modified by applying smoothing procedures.[12,59] The effects of truncation are most pronounced in the electrostatic energy, which falls off slowly with increasing distance. Schemes aimed at improved electrostatic energy calculations, including avoiding truncation effects are described in section 4.10. A decision about inclusion of bonded atom pairs in the nonbonded interaction list has to be made. Usually, atoms separated by one or two chemical bonds (so-called 1–2 and 1–3 interactions) are excluded from the nonbonded calculations, as it is assumed that the internal strain terms should describe their energetics sufficiently well. Atoms separated by three chemical bonds (1–4 interactions) are usually included, sometimes with modified values of the van der Waals parameters.[49] Finally, in order to reduce the number of nonbonded parameters, two parameters, typically a van der Waals radius and an interaction well depth are assigned to each atom. The parameters for pair interactions are then obtained from simple combination rules.[8]

For a peptide or protein system, the potential energy would involve the terms describing deformations of all the bonds, angles and dihedrals from their optimum values, as well as nonbonded interactions between atoms which are not chemically bonded, but are brought close together due to the three-dimensional folding of the molecule (tertiary structure). To simulate a solvated protein, we add additional terms in the potential, describing bond and angle deformations of the solvent molecules as well as solvent–solvent and solvent–protein interactions. It is truly amazing that such a simple functional form of the potential can describe the wide range of interactions occurring in macromolecules – formation of salt links, hydrogen bonds, solvation by polar and nonpolar solvents, complementary fitting of hydrophobic surfaces. The simple form is also misleading. For a protein of about
100 amino acids there might be 100 000 individual terms in the potential \( U \), and 500 000 terms if solvation by explicit solvent is considered. This is a complicated multidimensional function, the basic properties of which are not yet fully understood.

### 4.2 Energy Minimization

Energy minimization is a versatile tool of molecular modeling, used to identify stable structures, ensure consistency of model structures with a given potential, and remove thermal excitation from structures obtained from MD or MC simulations. An excellent introduction to the theoretical aspects may be found elsewhere, while examples of algorithms are presented in Flannery et al. 62

#### 4.2.1 Potential Energy Minima

The potential energy \( U(q) \) of a large molecular system depends on positions \( q \) of all atoms (3N coordinates for \( N \) atoms) and on a large number of parameters. A useful way of exploring properties of \( U \) and characterizing available molecular conformations is the identification of energy minima. A minimum of \( U(q) \) may be generally defined as some value of the coordinates \( q = q_{\text{min}} \) such that \( U(q) > U(q_{\text{min}}) \) for all possible values in some (possibly small) neighborhood of \( q_{\text{min}} \). By exploring different regions of variable space \( q \), we may identify a series of minima. These are called local minima; each corresponds to the lowest possible value of \( U \) in some local neighborhood of coordinate space. Of special interest is the global minimum, i.e. the minimum which corresponds to the lowest possible of all values of \( U(q) \). For functions of a large number of variables, the global minimum is rather difficult to find, see Wales and Scheraga 43 and below.

The minima represent possible stable structures of the molecular system. Rather than comparing some arbitrary structures in two different regions of conformation space, it is much more meaningful to compare energies of minima located in the two regions of interest. Some arbitrariness will always remain for large molecular systems, such as proteins, which have large numbers of local minima corresponding to a single macroscopically observable state, e.g. the “native form”. In that case we have to look at a sample of minima from each region of conformational space (e.g. the “folded structure”, “substrate bound structure”, “unfolded structure”).

Mathematically, energy minimization is a special case of a more general optimization problem: finding the lowest possible value for a function of many variables. The necessary condition for a minimum is that the function gradient is zero, as shown in Equation (2):

\[
\nabla U = g(q) = 0 \quad \text{or} \quad \frac{\partial U}{\partial x_i} = 0, \quad i = 1, 2, 3, \ldots, 3N
\]

where \( x_i \) denote atomic Cartesian coordinates and \( N \) is the number of atoms. The gradient \( g(q) \) is a vector with \( 3N \) components. Points at which the gradient is zero are called stationary points of a function. Besides minima, stationary points include maxima and saddle points.

The sufficient condition for a minimum is that the second derivative matrix is positive definite. Equation (3) shows that for any 3N-dimensional vector \( u \)

\[
\sum_{i,j=1}^{3N} F_{ij} u_i u_j > 0
\]

A simpler operational definition of this property is that all eigenvalues of \( F \) are positive at a minimum. The second-derivative matrix \( F \) is defined by Equation (4):

\[
F_{ij} = \frac{\partial^2 U}{\partial x_i \partial x_j}
\]

\( F \) is discussed further in section 4.4. One measure of the distance from a stationary point is the root mean square gradient shown in Equation (5):

\[
\text{GRMS} = \frac{1}{3N} \sum_{i=1}^{3N} \left( \frac{\partial U}{\partial x_i} \right)^2
\]

#### 4.2.2 Minimization Algorithms

Because \( U(q) \) is a complicated function varying quickly with atomic coordinates \( q \), molecular energy minimization is an iterative procedure, in which the coordinates at step \( n+1 \) are determined from coordinates at previous step \( n \), as shown in Equation (6):

\[
q_{n+1} = q_n + \delta_n
\]

where \( \delta_n \) is called a minimization step. The step may be determined in a number of ways in different minimization algorithms. The conceptually simplest approach is the steepest descent method. The step is performed in the direction of fastest local decrease of \( U \), i.e. opposite to the gradient \( g \), as shown in Equation (7):

\[
\delta_n = -\alpha_n g(q_n)
\]

where \( \alpha \) is a factor determining the length of the step. For multi-dimensional systems characterized by complex energy landscapes, this algorithm is rather inefficient; a relatively large number of iterations is needed to locate a local minimum. A whole family of conjugate gradient methods have been developed, which modify the steepest descent step in order to increase efficiency. The idea is
to make sure that the current step vector is not similar to the previous one, two or more step vectors. In the Fletcher–Powell algorithm the gradients from successive steps are used to form a numerical estimate of the second derivative matrix $F$ in order to speed up convergence. Since energy and gradient evaluations are a standard part of molecular mechanics codes, all these gradient-based methods carry a low computational cost per optimization step, but require a relatively large number of steps to complete.

A basic method which uses both the first and second derivatives of $U$ is the Newton–Raphson algorithm, which tries to predict the position $q_{n+1}$ at which the gradient will be zero, using the first-order Taylor expansion shown in Equation (8)

$$g(q_{n+1}) = g(q_n) + F \cdot (q_{n+1} - q_n) = 0$$

which leads to Equation (9)

$$q_{n+1} = q_n - F^{-1} \cdot g(q_n)$$

where $F^{-1}$ is the inverse of the second-derivative matrix $F$. The Newton–Raphson approach leads to fast convergence of the minimization. Its drawback is the necessity for evaluation and storage of the $3N \times 3N$ matrix $F$, which makes the method difficult to apply for large molecules. More efficient alternatives involve neglecting most of the small elements of $F$ (truncated Newton method) or limiting the matrix equations to a subspace of smaller dimensionality (e.g. adopted basis Newton–Raphson).\(^{12,60}\)

### 4.3 The Multiple Minimum Problem

The basic problem of molecular modeling is that the number of minima of a molecular potential energy function (i.e. the number of stable conformations) increases exponentially with the number of atoms $N$. This is known as the protein folding problem or global minimum problem.\(^{63,64}\) Several hundred distinct minima were found explicitly for a tetrapeptide in vacuum,\(^{65}\) a cluster of 55 Lennard–Jones atoms has an estimated $10^{10}$ minima,\(^{43}\) while the protein myoglobin explores a new potential energy minimum every 0.2 ps in a MD simulation at 300 K.\(^{66}\)

A simple example may be used to illustrate the multiple minimum problem. Consider a small protein of 100 amino acid residues. Let each amino acid be able to assume only two distinct conformers. The total number of protein conformations would then be $2^{100} \approx 10^{30}$. A processor on a good modeling workstation available in the year 1999 might perform about 10 energy evaluations per second for our system. Even if we had available a large number of much faster processors, and were able to perform as many as $10^{18}$ energy evaluations per second, testing all the conformers to find the lowest energy one would take $10^{12}$ s, or about 30,000 years.

The presence of such a large number of minima leads to severe difficulties in modeling properties of large, flexible molecular systems such as peptides and proteins. For example, in first principles protein structure prediction the global minimum of the molecular potential energy is sought as a model of the native, folded state.\(^{43}\) As the example above shows, finding the global minimum is impractical by simple systematic or random search techniques. Recent advances in specialized methods of global optimization for molecular systems are reviewed in Wales and Scheraga.\(^{43}\) Further discussion of problems related to multiple minima is presented in sections 4.5 and 4.6.

There are three additional complications in protein structure prediction. First, it is not certain that the native state corresponds to a global minimum or a local minimum in which the system has been kinetically trapped. Second, considering energies only ignores entropic effects; at finite temperatures we might expect the native form to be the free energy, rather than the energy minimum. Finally, there is no certainty that currently available potentials have sufficient accuracy to discriminate between folded and misfolded protein conformations.\(^{43}\) Simplified model calculations point to an important property expected of proteins that take on well defined three-dimensional structures: the global minimum should be separated from the rest of the minima by a significant energy gap.\(^{67}\) Such strong discrimination between the global minimum and the closest excited states has not been demonstrated so far in simulations at the atomic level of detail, which may be attributable to the crude models of solvation used so far. Although progress is being made, accurate, systematic structure prediction for complex systems such as large clusters, crystals or proteins is still not within reach of modeling techniques. Thus, experimental structural information is still needed as input in most molecular modeling studies.

A promising family of global optimization methods is based on the idea of deforming (smoothing, coarse graining) the potential energy surface. The smoothed energy surface is simpler than the original, allowing faster conformational exploration and identification of the global minimum. The different algorithms, such as the diffusion equation method, Gaussian phase packet, Gaussian density annealing, distance scaling method, conformational space annealing are reviewed in Wales and Scheraga\(^{43}\) and Straub.\(^{68}\)

### 4.4 Normal Mode Analysis

Normal mode analysis deals with systems executing small amplitude vibrations around an equilibrium position.
Under these conditions the potential energy may be taken to be a quadratic function of the coordinates and the physical system of $N$ interacting particles (atoms) becomes equivalent to a set of $3N$ independent harmonic oscillators. As a result, the dynamics and thermodynamics of the system may be determined in closed form. An excellent book on this topic is by Wilson et al.(1)

4.4.1 The Harmonic Approximation

For a molecule of $N$ atoms, described by $3N$ Cartesian coordinates $x_i, i = 1, 2, \ldots, 3N$, the kinetic energy is given by Equation (10)

$$ T = \frac{1}{2} \sum_{i=1}^{3N} m_i \dot{x}_i^2 $$

where $\dot{x}_i$ denotes the derivative of $x_i$ with respect to time. In the vicinity of the origin of the coordinates the potential energy $U$ may be expanded as a Taylor series in the powers of $x_i$. In the vicinity of the origin of the coordinates the potential energy $U(x = 0) = 0$ allows the representation of $U$ for small displacements around the origin in the form of Equation (11):

$$ U(x_1, x_2, \ldots, x_{3N}) = \frac{1}{2} \sum_{i=1}^{3N} \sum_{j=1}^{3N} \left( \frac{\partial^2 U}{\partial x_i \partial x_j} \right)_{x=0} x_i x_j $$

This is called the harmonic approximation. Here the linear term in the Taylor expansion is zero due to the condition that $U$ has a minimum at $x = 0$, and the higher order terms are neglected because they depend on higher powers of the small displacements $x_i$. The second derivatives of the potential energy with respect to atomic positions are the well-known harmonic force constants $F_{ij}$, already encountered in section 4.2.

4.4.2 Normal Coordinates

In principle, all the particles (atoms) in the system may interact with each other. Thus, all elements of the matrix $F$ may be non-zero, with the only condition being that $F_{ij} = F_{ji}$. The harmonic potential in Equation (11) couples together all coordinates $x$. Writing down Newton’s equation of motion in the $x$ coordinates leads to a set of $3N$ coupled differential equations. There exists a different set of coordinates $y_i, j = 1, 2, \ldots, 3N$ in which both the kinetic energy $T$ and potential energy $V$ have diagonal form, as shown in Equations (12) and (13):

$$ V(y_1, y_2, \ldots, y_{3N}) = \frac{1}{2} \sum_{i=1}^{3N} \lambda_i y_i^2 $$

$$ T = \frac{1}{2} \sum_{i=1}^{3N} y_i^2 $$

In these coordinates the equations of motion are uncoupled, i.e. they represent a system of $3N$ noninteracting quasi-particles, called normal modes.

The normal coordinates $y$ and the original Cartesian displacements from equilibrium $x$ are related by a linear transformation defined by a $3N \times 3N$ matrix $L$, as shown in Equations (14) and (15):

$$ x_i = \sum_{j=1}^{3N} L_{ij} y_j \quad \text{or} \quad x = Ly $$

$$ y_i = \sum_{j=1}^{3N} L^{-1}_{ij} x_j \quad \text{or} \quad y = L^{-1}x $$

$L$ is a matrix of constant coefficients, which depend, in principle, on all $N$ atomic masses $m_i$ and all $3N(3N + 1)/2$ harmonic force constants $F_{ij}$.

It is easy to show that the matrix $L$ is given by

$$ L = M^{-1/2}L' $$

where $M^{-1/2}$ is a diagonal matrix with inverses of the square roots of atomic masses on the diagonal as shown in Equation (17)

$$ (M^{-1/2})_{ij} = m_i^{-1/2} \delta_{ij} $$

with $\delta_{ij}$ the Kronecker symbol, while $L'$ is the matrix having as columns the eigenvectors of the mass-weighted Cartesian force constant matrix $F'$ ($F'_{ij} = (m_i m_j)^{-1/2} F_{ij}$). Equation (18) shows:

$$ FL' = L'A \quad \Lambda_{ij} = \lambda_i \delta_{ij} $$

The eigenvalues $\lambda_k, k = 1, \ldots, 3N$ of the matrix $F'$ are exactly the coefficients appearing in Equation (12).

4.4.3 Normal Modes

In the normal coordinate representation, the motion of the system (molecular nuclei) is a superposition of independent harmonic vibrations in each of the coordinates $y_i, i = 1, 2, \ldots, 3N$. These $3N$ types of motion are called the normal modes of the system. In the classical picture, the motion in the $k$th normal mode is a harmonic oscillation with cyclic frequency $w_k = \sqrt{\lambda_k}$, as shown in Equation (19)

$$ y_k(t) = A_k \cos(w_k t + \delta_k) $$

where the amplitude $A_k$ and phase $\delta_k$ are determined by the initial conditions. In the quantum picture, the energies $\hbar w_k$ represent possible excitations of the system from the ground state, observable in vibrational spectra.(1) The matrix $L$ contains a description of the form of motion:
\( L_{ik} \) gives the amplitude of displacement of the Cartesian coordinate \( x_i \) upon excitation of normal mode \( k \).

Describing vibrations in Cartesian coordinates is counterintuitive. The “natural” way to look at molecular vibrations is in the same way as we look at structure: in internal coordinates, i.e. deformations from equilibrium of chemical bonds, angles and dihedrals. Traditionally, vibrations of small molecules have been described in internal coordinates. Because of the difficulty of making the transformation to internal coordinates, vibrations of large molecules are traditionally described in Cartesian coordinates.

### 4.4.4 Anharmonic Effects

While the potential energy of a molecular system may be adequately represented by a quadratic function for small fluctuations, a full harmonic force field is needed to properly describe frequencies and forms of molecular normal modes.\(^1\) For larger amplitude motions anharmonic terms might be needed to correctly describe structural deformations, such as the Morse function for bond stretching.\(^8\) In comparison, the model potential in Equation (1) contains only the diagonal harmonic terms. Some force fields use more complicated forms for the bond stretching and angle bending terms (see MM3, CHARMM). However, the full harmonic potential is not employed in molecular mechanics, due to the number of parameters needed and their limited transferability. This limits the accuracy of calculated vibrational spectra, especially in the higher frequency range, corresponding to localized bond stretching and angle deformation modes. Usually, more effort is put into parameterizing low frequency vibrations, describing delocalized motions involving dihedral angle deformations. It is these motions that are of most interest, since they are related to conformational transitions in flexible molecules.\(^9\)

### 4.4.5 Applications

Protein motions cannot be described by classical harmonic vibrations at low temperatures (below 100 K), where quantum corrections need to be applied, or at room temperature over long timescales (over 100 ps), where hopping between different energy minima dominates.\(^61\) However, normal modes remain a useful tool in studies of peptide/protein structure and dynamics. Once the vibrational frequencies and normal modes are determined, the vibrational free energy and the mean atomic fluctuations may be calculated, and forms of collective motions of the systems proposed. Early studies looked at the structural fluctuations in \(\alpha\)-helices and \(\beta\)-sheets (see Brooks et al.\(^61\) for a review), as well modeling the mobilities of atoms in different parts of proteins, to compare with X-ray temperature factors.\(^21,22\) Differences in entropy between molecular structures were estimated based on normal mode analysis, e.g. for A and Z DNA.\(^69\) and the \(3_{10}\) and \(\alpha\) helices of an octapeptide.\(^70\) Low-frequency vibrational motions have been used as approximate reaction coordinates in complex systems, e.g. the inter-domain or “hinge-bending” motion in lysozyme\(^21,71\) and the \(\alpha\)-helix \(\rightarrow\) \(3_{10}\)-helix transition.\(^72\) Normal modes have also been employed to provide step directions in MC simulations\(^72\) and in algorithms for long time step MD.\(^73\) Detailed normal mode analysis of short model peptides aimed at understanding their vibrational spectra and improving model force field description of vibrations have also been performed.\(^74,75\)

### 4.5 Molecular Dynamics Simulations

MD simulations involve solving the equations of motion for a system of particles moving in a known potential \(U\). The discussion below deals with the case of Newton’s equations of classical mechanics. Other equations may also be used, which incorporate some average interactions with the environment (e.g. Langevin, Brownian dynamics\(^61\)). Newton’s equations provide a systematic way to generate a series of configurations of the simulated system corresponding the classical time evolution. These configurations not only provide information on the types of structures that may be sampled by the system (averages and fluctuations), but also completely describe the detailed dynamics of structural change and energy flow within the classical model, allowing calculation of time correlation functions and conformational transition rates.

#### 4.5.1 Numerical Solution of Newton’s Equations

Newton’s equations of motion for a system of \(N\) atoms can be expressed by Equation (20):

\[
m_i \ddot{\mathbf{r}}_i = m_i \frac{d^2 \mathbf{r}_i}{dt^2} = \mathbf{F}_i \quad i = 1, \ldots, N
\]  

(20)

where \(m_i\) is the mass, \(\ddot{\mathbf{r}}_i\) the acceleration, \(\mathbf{r}_i = (x_i, y_i, z_i)\) the position, and \(\mathbf{F}_i\) the force acting on atom \(i\), and \(t\) is the time. Given a potential \(U = U(q)\) describing the potential energy as a function of coordinates \(q\), the forces can be expressed as partial derivatives of \(U\) with respect to the atomic positions (i.e. components of the gradient):

\[
\mathbf{F} = -\nabla U = -\left( \frac{\partial U}{\partial x_i}, \frac{\partial U}{\partial y_i}, \frac{\partial U}{\partial z_i} \right) \quad i = 1, \ldots, N
\]  

(21)

A widely used and popular method of numerically solving Newton’s equations of motion (Equation 20) with the forces (Equation 21) is the Verlet algorithm,\(^76\) Equation (22), in which the position at time \(t + \Delta t\) is calculated from the positions at \(t - \Delta t\) and \(t\), and the forces at time \(t\):

\[
\mathbf{r}_{i,t+\Delta t} = 2 \mathbf{r}_{i,t} - \mathbf{r}_{i,t-\Delta t} + \mathbf{F}_{i,t} \Delta t^2
\]  

(22)
\[ \ddot{r}_i(t + \Delta t) = 2\ddot{r}_i(t) - \ddot{r}_i(t - \Delta t) + \frac{\ddot{F}_i}{m_i}(\Delta t)^2 + O((\Delta t)^4) \]  

while the velocity at time \( t \) is obtained from positions at 
\( t - \Delta t \) and \( t + \Delta t \), as shown in Equation (23):

\[ \dot{v}_i(t + \Delta t) = \frac{\ddot{r}_i(t + \Delta t) - \ddot{r}_i(t - \Delta t)}{2\Delta t} + O((\Delta t)^2) \]  

The above equations provide a numerical solution for 
Newton’s equations of motion by generating positions 
\( \ddot{r}_i \) while the velocity at time \( t \) and velocities 
\( \dot{v}_i \) at times \( t + \Delta t \), \( t + 2\Delta t \) \ldots Such solutions are usually called trajectories 
of the simulated system. Trajectories generated using the 
Verlet algorithm have very interesting properties similar 
to those of the exact solutions.\(^{(77)}\) Other algorithms in use 
include velocity Verlet and leapfrog.\(^{(78)}\)

### 4.5.2 The Timescales

There are two extreme timescales involved in MD 
simulations. The shortest timescale is the integration 
time step \( \Delta t \), while the longest one is the total length 
of the simulation \( \tau \). The length of the time step is 
determined by the numerical algorithm used and the 
highest frequency motions present in the simulated 
system. For typical biological or organic molecules, 
with or without solvent, the highest frequency motions 
correspond to stretching and bending of bonds involving 
hydrogen atoms and stretching double bonds. X–H 
(\( \text{C–H, O–H, N–H, \ldots} \)) stretching frequencies fall in the 
3000–3600 cm\(^{-1} \) range, X–H bending and double bond 
stretching (\( \text{C–O, C=C, C=N, \ldots} \)) in 1400–1800 cm\(^{-1} \).\(^{(79)}\) 
The period of a 3300 cm\(^{-1} \) vibration is equal to 10 fs 
(1 fs = 10\(^{-15} \) s). In standard approaches, to obtain an 
accurate numerical solution to the equations of motion 
the integration time step must be much smaller that this 
value. Thus, typical integration time steps \( \Delta t \) of 1 fs or 
less are usually used.\(^{(18,61)}\) Elimination of the highest 
frequency X–H stretching motions through application of 
constraint algorithms such as SHAKE or RATTLE 
allows the use of the 2 fs time step.\(^{(78,80)}\) Since the forces 
have to be evaluated at every time step, longer simulations 
could be performed at the same cost if \( \Delta t \) were increased. 
This goal is being addressed by several novel approaches 
described at the end of this section.

Ideally, the total length of the simulation \( \tau \) should be 
at least comparable to the timescale of the phenomenon 
under study. For peptide and protein systems this has 
rarely been the case so far, and the current standard of 
1–10 ns length simulations is determined mainly by 
the computational cost. Such trajectories are useful in 
predicting structures and conformational dynamics of 
short peptides (2–6 residues), but are of insufficient 
length for many phenomena in larger peptides or 
proteins. For example, helix formation in peptides has 
been observed on the 100 ns timescale, the structural 
changes in hemoglobin accompanying oxygen binding 
take place in the microsecond to millisecond range 
(10\(^{-6} \) to 10\(^{-3} \) s), and different stages of folding of small 
globular protein have been characterized on millisecond 
to second timescales. Special simulation techniques which 
enable simulation of large scale structural transitions 
occurring over long timescales are briefly described 
in sections 4.8 and 7. Difficulties of conformational 
exploration are compounded by the fact that not only 
are there multiple minima, but the energy landscape is 
rugged, with different regions separated by barriers with 
a wide range of heights. This leads to problems of kinetic 
trapping and the necessity to sample rare barrier crossing 
events.\(^{(42)}\)

### 4.5.3 System Preparation

To start a simulation, we need initial coordinates and 
velocities for all atoms. The starting structure is usually 
obtained from X-ray crystallography or NMR 
experiments.\(^{(47,61)}\) First, energy minimization is performed, 
to assure consistency of the structure with the 
potential energy function employed, and to bring the 
coordinates close to a local minimum, where forces acting 
on atoms are small. The next stage is heating, consisting 
of a series of consecutive random velocity assignments 
from Maxwell–Boltzmann distributions corresponding 
to increasing temperatures, interspersed with periods of 
unperturbed dynamical evolution. The purpose of this 
phase is to bring the system close to the desired final tem-
perature and evenly distribute kinetic energy throughout 
the macromolecule. Heating is followed by an equilibra-
tion phase, when the system is allowed to evolve, with 
temperature (and other variables, if needed) monitored 
and adjusted as necessary to the desired target value. 
The equilibration is usually assumed to be complete when 
the monitored properties of the system do not change in 
a systematic way. In MD simulations, the temperature 
\( T \) is defined through the kinetic energy \( K \), as shown in 
Equation (24):

\[ K = \frac{1}{2} \sum_{i=1}^{N} m_i v_i^2 = \frac{1}{2} f k_B T \]  

where \( k_B \) is the Boltzmann constant and \( f \) is the number 
of degrees of freedom. This formula is obtained using the 
classical equipartition theorem.\(^{(83)}\) For a free molecule, 
usually \( f = 3N - 6 \) usually, since we eliminate the overall 
translations and rotations; for a system under periodic 
boundary conditions (PBC) \( f = 3N - 3 \), since rotations 
are no longer free. The final stage of a simulation is the 
generation of a trajectory which will be used to analyze
the properties of interest. The trajectory is simply a set of coordinates (and possibly velocities) of the system, providing “snapshots” of its time evolution.

4.5.4 Information Content of a Trajectory
A significant amount of information can be derived from MD simulations. Since we are solving Newton’s equations of motion, the resulting dynamics represents the true classical time evolution of our system, yielding forms, amplitudes, timescales and energetics for different microscopic events, such as atomic fluctuations, side chain rotations, helix–helix reorientations, etc. which occur within the time frame of the simulation. The time course of the dynamics is usually described in terms of time correlation functions, which are related to observable dynamical properties. Trajectory averages of dynamical quantities – structural parameters, energies and their fluctuations – correspond to the observed values of these quantities.

4.5.5 Time Correlation Functions
For a time dependent quantity $A(t)$ the autocorrelation function is defined by Equation (25):

$$C_{AA}(\tau) = \langle A(0)A(\tau) \rangle$$  \hspace{1cm} (25)

where $\langle \cdots \rangle$ denotes averaging over the initial times $t = 0$. Time correlation functions are related to a variety of observable dynamical quantities, e.g. the translational diffusion coefficient is shown by Equation (26):

$$D_t = \frac{1}{3} \int_0^\infty \langle \ddot{v}(0)\ddot{v}(\tau) \rangle \, d\tau$$  \hspace{1cm} (26)

where $\ddot{v}$ is the velocity of the molecular center of mass, and the rotational diffusion coefficient is given by Equation (27):

$$D_r = \frac{1}{3} \int_0^\infty \langle \ddot{w}(0)\ddot{w}(\tau) \rangle \, d\tau$$  \hspace{1cm} (27)

where $\ddot{w}$ is the angular velocity of the center of mass. Formulae for reaction rates, dielectric relaxation, vibrational frequencies and other spectroscopic parameters have been obtained. Examples of correlation functions are shown in Figure 2.

4.5.6 Trajectory Averages
Most experimental measurements are performed not on individual molecules, but on macroscopic samples. As a result, observed macroscopic quantities are averages, both over the molecules in the sample and over the timescale of the measurement. For systems at equilibrium, statistical mechanics provides a connection between such averages and properties of microscopic states, which are directly sampled in simulations. In the canonical ensemble, describing a system at constant number of particles $N$, volume $V$ and temperature $T$ (NVT), the probability distribution for finding the system in a microscopic state corresponding to a set of particle momenta $p$ and positions $q$ is given by the well known Boltzmann formula shown in Equation (28)

$$\rho(p, q) = \frac{e^{-H(p, q)/k_BT}}{dp \, dq \ e^{-H(p, q)/k_BT}}$$  \hspace{1cm} (28)

and the ensemble average of any quantity $X(p, q)$ is given by Equation (29)
The function of Hamiltonian, which gives the energy of the system as a function of the momenta (velocities) is given by Equation (30):

$$\rho(q) = \frac{e^{-U(q)/k_BT}}{dq e^{-U(q)/k_BT}}$$  \hspace{1cm} (30)

which gives for an average of a physical quantity $Y(q)$ which depends on positions only, as shown in Equation (31):

$$\langle Y \rangle = \frac{dq Y(q)\rho(q)}{\rho(q)}$$  \hspace{1cm} (31)

In the equations above $H(p, q) = K(p) + U(q)$ is the Hamiltonian, which gives the energy of the system as a function of $p$ and $q$, $k_B$ is the Boltzmann constant, $K$ is the kinetic energy, and $U$ the potential energy. In calculating ensemble averages we are considering an infinite number of copies of our system prepared with different initial conditions at a fixed point in time.

Ensemble averages may be directly evaluated from MC simulations of many-particle systems (see section 4.6). In MD simulations we can directly evaluate time (or trajectory) averages, defined as Equation (32):

$$\bar{X}_t = \frac{1}{t_0} \int_0^t X(\tau) d\tau \approx \frac{1}{N_t} \sum_{k=1}^{N_t} X(t_k)$$  \hspace{1cm} (32)

where $X(\tau) = X(p(\tau), q(\tau))$ is the value of quantity $X$ at time $\tau$ and the final equation shows how in practice the time average is estimated as the arithmetic average over the $N_t$ trajectory points $t_k$, $k = 1, \ldots, N_t$ ($t = N_t \Delta t$). Thus, in MD the time evolution of a single copy of the system is determined and $X$ is averaged over the microstates sampled in the trajectory.

The ergodic hypothesis states that these two averages should be equivalent in the long time limit,$^{86}$ as shown in Equation (33):

$$\langle X \rangle = \bar{X} = \lim_{t \to \infty} \bar{X}_t$$  \hspace{1cm} (33)

Real computer simulations can only be propagated for finite time intervals, sampling a part of available structures, and providing approximate estimates of true averages. If the finite set of configurations and momenta sampled during a simulation is able to correctly reproduce the properties of the system, it is called a representative sample. To check whether a given sample is representative, the usual way is to compare calculated and observed properties of the simulated system, monitor averages for systematic change, and compare results from separate trajectories started from different initial conditions. That configuration samples obtained by MD simulations are usually representative follows from the method of preparing the trajectory and from Equation (21). Since the forces acting on the atoms are driving them towards regions of lower potential energy $U$, we expect that after neglecting the initial heating and equilibration phase, the system will sample regions of relatively low $U$. These are the physically most meaningful configurations, which have the largest weights in the ensemble average (Equations 29 and 31). MD simulations may thus be envisioned as a systematic method of sampling system configurations. It must be underlined that due to the enormous number of states available to a large molecular system, we can never be sure that all important structures have been sampled in a simulation of finite length.

4.5.7 Equilibrium versus Nonequilibrium Dynamics

MD simulations may be used to study two general classes of motion – equilibrium fluctuations and nonequilibrium, or relaxation type dynamics. The first type of motion may be generated by the procedure described above, where the system was carefully prepared in a conformation close to the experimentally observed (and presumably biologically active) one, with a random thermal distribution of velocities. The simulated dynamics is then expected to model thermal fluctuations at equilibrium of the experimental system. To understand the difference between equilibrium and nonequilibrium dynamics, let us consider the standard example of irreversible gas expansion.$^{86,87}$ The gas initially occupies one part of the volume of a container divided by a partition. After the partition is removed, the gas irreversibly expands to fill the whole available volume. Analogously, in simulations of nonequilibrium dynamics, we prepare a system in a nonequilibrium state and follow its time evolution as it relaxes towards a new equilibrium. This nonequilibrium initial state may have unequal distributions of kinetic$^{88}$ or potential energy.$^{89–92}$ Observations of relaxation in a macroscopic sample will provide results averaged over the constituent molecules. The individual molecules will generally exhibit somewhat different timescales and pathways of relaxation, due to differences in their initial conditions. In order to adequately simulate observed relaxation phenomena, it is not sufficient to calculate a single long trajectory, since the system will tend to reach its new equilibrium after some characteristic time. Rather, it is necessary to generate a number of independent trajectories, starting with different initial conditions, and obtain from them the average time evolution. Clearly, variations in relaxation timescales and pathways between the different

Trajectories also constitute valuable information about
properties of the studied system. Sample results of a
nonequilibrium relaxation are shown in Figure 3.\(^{(93)}\)

4.5.8 Constant Temperature and Pressure Molecular
Dynamics

The simplest MD simulation protocol involves solution of
Newton’s equations of motion, as described above. The
simulation conditions correspond roughly to the micro-
canonical ensemble of statistical mechanics, i.e. constant
energy \( E \), number of particles \( N \) and volume \( V \).\(^{(18,78)}\) For
some processes, more realistic conditions would involve
constant temperature \( T \) or constant temperature \( T \) and
pressure \( P \). Several different approaches have been de-
developed that allow constant temperature and/or constant
pressure simulations. These approaches involve some

sort of adjustment to the kinetic energy (Equation 24) or
the virial.\(^{(18,78)}\)

4.5.9 New Molecular Dynamics Algorithms

Several approaches are being pursued in development of
novel numerical algorithms for MD. Progress has been
achieved in understanding the fundamental properties of
the dynamics in nonlinear systems. One aspect that
has emerged is that it is desirable to develop numerical
algorithms which have mathematical properties of
the original dynamical equations, such as being sym-
plectic (conserving volume in phase space\(^{(94)}\)) or time
reversible.\(^{(42)}\) Symplectic numerical algorithms display
exceptional long-term stability. Thus, while high-order
nonsymplectic algorithms may be formulated that give
more precise solutions with smaller local energy fluctu-
ations, the symplectic methods have smaller long-term
energy drift.\(^{(73)}\) Time reversible algorithms have become
the basis of the whole family of force splitting or multiple
time stepping (MTS) methods such as the reversible re-
ference system propagator algorithms (r-RESPA).\(^{(42)}\) In
the MTS approach the forces in the system are split into
several categories – fast and slow, long and short range.
Each category is associated with a timescale. Thus, the
fast forces (due to bond stretching and angle bending) are
evaluated every time step \( \Delta t \), and the slow forces (dihe-
dral deformation and nonbonded interactions) every \( m \Delta t \)
steps. By choosing \( \Delta t = 0.5 \text{ fs} \) and \( m = 5–6 \) integration
of the equations of motion becomes more accurate, since
the relatively few highest frequency terms are evaluated
more often, and cheaper, since the most costly nonbonded
term is evaluated less often than with a standard simul-
imation with a single time step of 1 fs. Analogous effects are
obtained by updating more often the strong but relatively
few in number nonbonded interactions of an atom with
its nearest neighbors and less often the weaker but more
numerous interactions with more distant atoms. Combin-
ing these two subdivisions leads to significant acceleration
of computations, by factors of 5–40, dependent on details
of the studied system.\(^{(42)}\) The additional advantage is that
the MTS methods allow the abandonment of SHAKE
constraints, together with their modifying influence on
the system dynamics. Using MTS methods, a 4–5 fs limit
may be reached for the time step of updating the slowest
(and most costly) force component. Further extension of
the time step in Newtonian dynamics appears to be
difficult, as instabilities arise due to resonances with the
highest frequency motions.\(^{(73)}\) One approach of further
extending the time step is based on time averaging of
the forces.\(^{(95)}\) Other approaches use normal modes to
describe the high frequency motions: analytical normal
vibrations combined with MTS\(^{(96)}\) or efficient numerical
normal vibrations with force extrapolation and splitting,
combined with using stochastic dynamics to eliminate
effects of resonance.\(^{(73)}\)

Difficulties arise when attempts to assess accuracy of
MD trajectories are made. We are simulating model
systems, with potentials that only approximate real
molecules. Thus, it is not clear that highly accurate
simulations are really necessary. The motion of nonlinear
systems is chaotic, i.e. trajectories starting from very
similar initial coordinates will eventually diverge to some
maximum distance.\(^{(18,73)}\) Thus, it appears that statistical
measures, such as spectral densities of dynamical variables
are the most appropriate quantities for comparison.

4.6 Monte Carlo Simulations

MC methods may be defined as ways of calculating
integrals using special types of random sampling.\(^{(97)}\)

Figure 3 Time course of Fe atom displacement out of heme
plane subsequent to CO dissociation from CO–myoglobin.\(^{(93)}\)
Noisy solid line – average evolution from four 100 ps MD
trajectories smoothed with a 2 ps running window. Smooth
solid line – fit with two-exponential decay. Dashed lines – the
two-component exponentials. (Adapted from K. Kuczera
et al\(^{(97)}\))

Trajectories also constitute valuable information about
properties of the studied system. Sample results of a
nonequilibrium relaxation are shown in Figure 3.\(^{(93)}\)
The integrals in question are of the type given by Equations (29) and (31). In molecular simulations MC methods are used to generate representative samples of possible system structures with the correct distribution corresponding to a given temperature. The averages and fluctuations of structural or energetic parameters calculated numerically over such a sample should then correspond to statistical mechanics ensemble averages on the theoretical side and to experimental observables on the empirical side. For systems with a large number of atoms \( N \), e.g. \( N = 100–1000 \), numerical evaluation of the averages of the type shown in Equations (29) and (31) becomes impractical by simple grid or random approaches. In the grid method some number \( m \) of values is sampled for each coordinate involved. The total number of points (structures) sampled is then \( m^{3N} \), which becomes prohibitively large even with \( m = 2 \). When random samples of structures are used, it is found that most points have a high potential energy \( U \) and do not contribute significantly to the average (Equation 31) due to a low Boltzmann factor. \(^{197}\)

4.6.1 Markov Chains

The MC solution to these difficulties is to create samples of structures that are partly correlated – so-called Markov chains, which may be defined in the following way. Label the possible states of the system (structures): \( q_1, q_2, \ldots, q_i, \ldots \). Consider a random walk over the states, which reaches state \( q_i \) at step \( k \). If the probability \( P_q \) of reaching a given state \( q_i \) in the next step \( k+1 \) of the walk depends only on the current state \( q_i \) (and not on the states reached at previous steps \( k-1, k-2, \ldots \)), then the random walk is called a Markov process. \(^{198}\) The set of states explored in a Markov process is called a Markov chain. The advantage of Markov chains is that the transition probability \( P_q \) may be adjusted so that a large fraction of sampled points correspond to large weights in the target average.

4.6.2 Metropolis Monte Carlo

In the widely used Metropolis MC method for the algorithm of generating the Markov chain, we start with the system in state \( q_i \) at step \( k \). The current system configuration \( q_i \) is then perturbed in a random way to generate a new trial configuration \( q'_i \). The potential energies \( U(q_i) \) and \( U(q'_i) \) are compared. If the trial configuration has a lower energy, it is accepted, i.e. the state of the system at step \( k + 1 \) is set to \( q'_i \) again. The probability \( P \) is given by Equation (34):

\[
P = \frac{e^{-U(q'_i)/k_B T}}{e^{-U(q_i)/k_B T}} = e^{[U(q'_i) - U(q_i)]/k_B T} \quad (34)
\]

As long as the perturbations used to generate trial configurations obey some simple conditions, it can be shown that in a sufficiently long simulation the ratio of probabilities of finding any two structures \( q_i \) and \( q_j \) in a sample generated by the Metropolis MC method is given by Equation (35):

\[
\frac{P(q_i)}{P(q_j)} = e^{[U(q_i) - U(q_j)]/k_B T} \quad (35)
\]

i.e. it is equal to ratio of Boltzmann factors, the same as would be expected in the canonical ensemble. Due to this property we can calculate statistic mechanical averages directly from the sample of structures generated in the MC simulation. Equation (36) shows that for any quantity \( Y(q) \) which is a function of particle positions only

\[
\langle Y \rangle = \frac{1}{M} \sum_{i=1}^{M} Y(q_i) \quad (36)
\]

The MC simulation yields a sample of structures from which we can obtain statistics. The method of generating the Markov chains assures us that a large fraction of sampled conformations correspond to high Boltzmann factors, where the integrand is appreciably different from zero.

4.6.3 Convergence

Theoretically, infinitely long MD or MC simulations will provide the complete classical characterization of the system with a given model potential \( U(q) \). In a finite simulation we never explore all possible conformations or all possible motions/fluctuations, since we do not know what structures or motions have been missed, and can never be completely certain that we have a representative sample of microscopic states which can be used to characterize the observable macroscopic properties. In finite simulations the choice of the starting point and the length of the simulation become important. Especially difficult is the problem of sampling the rare barrier crossing events, corresponding to high relative values of \( U \) and low Boltzmann factors.

4.7 Conformational Search

Conformational search aims to determine the lowest energy structures of flexible molecular systems. In studies of biological and organic molecules the chemical bond lengths and angles do not vary significantly between
The free energy is a fundamental quantity in chemistry and physics. Free energy differences between different

![Figure 4 Adiabatic $\phi - \psi$ map of the alanine dipeptide. (Produced using CHARMM program and parameters.)](image)
molecular states are related to equilibrium constants (through thermodynamics) and kinetic rates (through transition state theory). In recent years computational methods have been proposed which make possible calculation of free energy changes from computer simulations of molecular systems. For reviews of methods and applications refer to the literature. Typical biomolecular applications for which free energy simulations have met with success involve two kinds of processes – structural transitions and chemical change. In structural transitions the chemical nature of the system does not vary, and the process is followed by evaluating the free energy profile PMF (potential of mean force) along a selected reaction coordinate, e.g. a dihedral angle for a conformational transition, a distance between two species for aggregation. The PMF provides direct information on the free energy differences between various stable conformers as well as about the free energy barriers that separate them. These data can then be converted into population ratios and transition rates. In simulations of chemical change, or mutations, the free energy change of substituting one chemical group with another in a condensed phase system (crystal, solution, protein) is evaluated. This allows predictions of such effects as influence of point mutations on thermal stability and ligand binding of proteins, or role of different substituents in determining the affinity of an inhibitor for a target enzyme.

Free energy simulations have two main advantages relative to standard simulation approaches. First, free energy values are obtained, rather than just energies. The free energies are directly related to experimental observables – binding affinities, population ratios, rate constants. Second, the free energy differences obtained may be much more precise than energy values. This follows from some special properties of the evaluation algorithms, as described below. Additionally, the structural transition simulations provide a way to partially overcome the conformational sampling problem. Namely, using free energy simulations of feasible length, the system may be forced to overcome quite high barriers along a reaction coordinate, effectively reaching states that are practically inaccessible in a direct simulation. As with all modeling approaches free energy simulations are able to provide important insights and improved understanding of complex macromolecular processes, such as ligand binding, folding, aggregation, solvation and mutation by decomposing the total free energy change into contributions from solvent, protein and even individual residues, chemical groups or atoms. Free energy simulations also share some shortcomings with the other modeling techniques. Obviously, any simulation, free energy or otherwise, is as reliable as the underlying potential function. To obtain reliable estimates of free energies, representative samples of system structures still have to be generated, which is difficult due to the problem of multiple minima. Although sampling along the reaction coordinate may be accelerated, exploration of conformational space in the orthogonal direction proceeds at the same pace as in standard MD or MC simulations.

Fundamentally, the free energy is related to the statistic mechanical partition function, i.e. the sum of weights of all possible states. To circumvent the difficult problem of calculating absolute value partition functions, free energy simulation methods concentrate on calculating their ratios, which yield the differences between free energies of thermodynamic states for molecular systems. Since free energies are functions of state, their changes can be evaluated along any path connecting the two states under consideration; the path can be chosen so as to make calculations easiest. The Gibbs free energy $G$ is the appropriate function under constant temperature and pressure, while the Helmholtz free energy $A$ is used at constant temperature and volume. In condensed phase systems, such as proteins or peptides in solution or crystal, we expect that $\Delta G \approx \Delta A$.

4.8.2 The Coupling Parameter

The three main approaches to free energy calculations are thermodynamic perturbation (TP), thermodynamic integration (TI) and umbrella sampling. In TI and TP a coupling parameter $\lambda$ is introduced to construct a hybrid potential energy function $U(q, \lambda)$. For conformational processes the parameter $\lambda$ is an actual structural coordinate, e.g. a distance between two atoms or a dihedral angle; $U(q, \lambda)$ then represents the potential energy corresponding to a fixed value of the chosen coordinate, with all other coordinates $q$ allowed to vary. For mutation processes, in which the chemical structure of the system is modified, $U(q, \lambda)$ mixes the properties of the two molecular states in such a way that varying $\lambda$ from 0 to 1 changes the potential energy function from that of the initial state $U_0$ to the final state $U_1$. In this case the intermediate states are artificial constructs having a potential i.e. a mixture of the initial and final state potentials. The simplest way to do this is the linear coupling approach shown in Equation (37):

$$U(\lambda) = (1 - \lambda)U_0 + \lambda U_1 = U_0 + \lambda(U_1 - U_0)$$  \hspace{1cm} (37)

Simulations are performed for a series of values of the coupling parameter $\lambda$; each such simulation is called a step or window.

4.8.3 Thermodynamic Perturbation

In the TP approach the free energy difference between states corresponding to $U(q, \lambda)$ and $U(q, \lambda'')$ we use
Equation (38), 

\[ \Delta G(\lambda' \rightarrow \lambda'') = -k_B T \ln e^{-\beta [U(\lambda') - U(\lambda'')]} \]  

(38)

where the angled brackets signify a statistical ensemble average for a system with potential energy \( U(q, \lambda') \). As usual, this is estimated numerically by a trajectory average of an MD simulation (or sample average of an MC simulation) over the window corresponding to \( U(q, \lambda') \). The total free energy change is calculated using Equation (39) by accumulating the differences between windows so as to span the whole interval between 0 and 1:

\[ \Delta A = \sum_k \Delta A_k \]  

(39)

The formula in Equation (38) involves averaging over all possible configurations, or, equivalently over infinitely long trajectories (Equation 33). In simulations, we always work with limited samples and finite trajectories. With sufficiently careful preparation, involving choice of starting structure, energy minimization, heating and equilibration, a representative sample of configurations of the initial state can usually be generated by MC or MD simulations. In order to obtain an accurate estimate of the average from the TP method, Equation (38), these same configurations also have to be representative for the final state. To assure this condition, in practical applications the perturbation from the initial to the final state is not performed in a single step, but is broken up into several stages, with introduction of one or more intermediate states. This is called multistep or multiwindow TP. It should be noted that we only need to have simulations for the starting values \((\lambda')\) of the coupling parameter in Equation (38), while the end-points \((\lambda'')\) are arbitrary. Thanks to this property, simulations for the initial \((\lambda = 0)\) and final \((\lambda = 1)\) states are not necessary to calculate \( \Delta G \). Another consequence is the possibility of using the double-wide sampling technique, in which one evaluates the free energy changes half a step forward and half a step backward in \( \lambda \). This procedure reduces the size of the perturbation and leads to more accurate free energy differences. If the initial and final surfaces are approximately parallel, we can expect to obtain good estimates of the free energy change even for large values of \( \Delta G \) and relatively small samples of configurations. Novel approaches which use special “soft potentials” enable evaluations of many perturbations from a single simulation.

4.8.4 Thermodynamic Integration

In the TI approach the derivative of the free energy with respect to the coupling parameter \( \lambda \) is evaluated. Equation (40) shows that for mutational processes, when \( \lambda \) is an additional external coordinate:

\[ \frac{\partial G(\lambda)}{\partial \lambda} = \frac{\partial U(\lambda)}{\partial \lambda} - k_B T \frac{\partial \ln J(\lambda)}{\partial \lambda} \]  

(40)

i.e. the derivative of the free energy with respect to the coupling parameter \( \lambda \) is equal to the average of the corresponding derivative of the hybrid potential over the ensemble for the system with potential \( U(\lambda) \). For conformational processes, for which \( \lambda \) is an internal coordinate which is also involved in defining the system configuration we obtain Equation (41):

\[ \frac{\partial G(\lambda)}{\partial \lambda} = \frac{\partial U(\lambda)}{\partial \lambda} - k_B T \frac{\partial \ln J(\lambda)}{\partial \lambda} \]  

(41)

where the averages are evaluated over configurations with a fixed, definite value of \( \lambda \). According to Equation (41), the derivative of the free energy with respect to the conformational coordinate involves the averages of two terms: the derivative of the potential with respect to the reaction coordinate \( \lambda \) and a term involving the Jacobian of the coordinate transformation between \( \lambda \) and atomic Cartesian coordinates. The Jacobian term is easily evaluated analytically for distance coordinates and has been found to be negligible for dihedral angle coordinates. Proceeding analogously as in TP, simulations are performed for several intermediate states or windows with different values of \( \lambda_i \). These simulations yield samples of configurations over which we can estimate the averages involved. The desired \( \Delta G \) between the final and initial states is obtained using Equation (42) by numerical integration of the derivative:

\[ \Delta G = \int_0^f \frac{\partial G(\lambda)}{\partial \lambda} d\lambda \approx \sum_k \left( \frac{\partial G(\lambda)}{\partial \lambda} \right)_k \Delta \lambda_k \]  

(42)

where the summation is over the windows \( k \), and the integral bounds are \( i = 0 \) and \( f = 1 \) for mutation processes, and \( i = \lambda_0 \) and \( f = \lambda_1 \) (the initial and final values of the reaction coordinate) for conformational processes. While for mutation processes the quantity \( G(\lambda) \) is just a computational device for the calculation of \( \Delta G \), for conformational processes \( G(\lambda) \) has physical meaning – it is the conformational free energy, or PMF along the reaction coordinate \( \lambda \).

An advantageous property of the TI method is that Equation (42) is linear in potential energy. This allows free energy changes to be decomposed into contributions from the different terms in the potential energy function (bond stretching, angle and dihedral deformation, van der Waals and electrostatic) as well as different parts of the system (solvent, protein, donor and acceptor chains, individual residues). Decompositions allow insight into the microscopic details of the studied.
phenomena. Such decompositions are not rigorous. Only the overall free energy is a thermodynamic function of state and corresponds to an experimental observable. The values of the different components may depend on the force field parameterization and on the path connecting the initial and final thermodynamic state. Nevertheless decompositions are widely used to provide qualitative insight into the microscopic mechanism of the studied phenomena. An additional property of the TI method is that it is completely local, i.e. we only have to consider whether the simulations provide representative samples for the current value of \( \lambda \) (whereas in TP the sample also has to be representative for the neighboring windows). In practice, comparable results are obtained when TP and TI approaches are used to extract free energy values from the same data set.\(^{26,119}\)

4.8.5 Umbrella Sampling

The umbrella sampling method differs from TI in that the reaction coordinate is not fixed, but restrained to remain in a limited range of values by a constraint potential \( U_c(\lambda) \).\(^{97,119}\) Thus, the simulations are performed in an effective potential \( U^* \), given by Equation (43)

\[
U^* = U(q) + U_c(\lambda)
\]

(43)

where \( U(q) \) is the molecular potential function and the constraint potential \( U_c \) is some (usually simple) function of the reaction coordinate \( \lambda \), given by Equation (44):

\[
U_c = k(\lambda - \lambda_{\text{ref}})^2
\]

(44)

where \( k \) is a force constant and \( \lambda_{\text{ref}} \) is a reference value around which we wish to sample values of \( \lambda \). Simulations with \( U^* \) are employed to calculate the corresponding biased distribution \( P^*(\lambda) \) of the reaction coordinate in the vicinity of \( \lambda_{\text{ref}} \). This distribution is then used to calculate the PMF or conformational free energy \( G(\lambda) \) in the unbiased potential \( U \) by Equation (45):\(^{97,119}\)

\[
G(\lambda) = -k_B T \ln P^*(\lambda) - U_c + \text{const}
\]

(45)

The arbitrary constant in the equation above is different for every simulation window. Values of the constants are determined from the condition that probability densities from neighboring windows overlap.\(^{119}\) By calculating a series of windows with different values \( \lambda_{\text{ref}} \) which have overlapping distributions \( P^*(\lambda) \), the free energy profile (or PMF) \( G(\lambda) \) for the process corresponding to the motion of the system along the reaction coordinate may be generated.

One additional difficulty appears for the mutational processes. The potential energy parameters refer to a given electronic state of a fixed covalent chemical structure, and we cannot use classical potentials to calculate electronic energy differences between such different structures. This difficulty can be overcome through the use of thermodynamic cycles.\(^{120}\) Calculating the difference \( \Delta \Delta G \) of the effects of the same mutation process in two different environments, such as protein interior and solution, the unphysical terms are cancelled out, leaving only the physical contributions from the changed interactions with the environment.

An interesting feature of free energy simulations is that the free energy values obtained are more precise than the corresponding energy values. This appears to be due to the fact that only those energy terms that directly vary with the coupling parameter/reaction coordinate \( \lambda \) contribute to Equations (38), (40), (41) and (45). Also, it is found in practice that the accuracy of components is usually lower than that of the total free energy change. This is true both for the unphysical components, such as electrostatic or solvation free energies, but also for thermodynamic functions such as entropy \( S \) and enthalpy \( H \) when extracted from \( \Delta G = \Delta H - T \Delta S \).

4.9 Solvation and Environmental Effects

Peptides, proteins and other biomolecules realize their functions in a condensed phase molecular environment, such as aqueous solution, lipid membrane or macro-molecular aggregate. An example of the influence of solvent on biomolecular properties is the recognition of the hydrophobic effect (i.e. clustering together of nonpolar groups to exclude water) as the major driving force in protein folding.\(^{64}\) Current molecular simulations employ a host of methods to include the influence of the external molecular environment (the “solvent”) on the modeled system of interest (the “solute”).\(^{99,121}\)

4.9.1 Explicit Solvent Methods

Conceptually simplest are explicit solvent methods. Here the solvent is treated in full atomic detail, on par with the solute. On the level of the model potential \( U \) (Equation 1), additional terms appear, describing internal deformations of the solvent molecules as well as solute–solvent and solvent–solvent nonbonded interactions. Within the explicit solvent approach the problem of dealing with the system boundary may be dealt with in several ways.\(^{118,61}\) An elegant solution is to use PBC, in which the simulated system is placed in a space-filling cell (the primary cell) surrounded by translational copies of itself (images). Image atoms within the nonbond cutoff distance of a primary atom are included in calculating the nonbonded interaction energy. The image atoms thus provide a molecular environment for primary atoms close to the cell surface. Since image atoms are not independent entities but translational copies of primary atoms, this procedure effectively introduces correlations
between primary atoms at opposing cell surfaces. To minimize this correlation, in cutoff-based methods the minimum image convention is usually applied, in which each primary atom does not interact with itself and interacts with, at most, one image (the closest) of any other atom in the primary cell. The most widely used are the cubic and truncated octahedral cell, although other shapes have been proposed. An example of a simulation cell is presented in Figure 5. In the cubic cell, the minimum image convention is satisfied when the non-bond cutoff is less than half the cell size. The advantage of the PBC approach is that a realistic molecular environment is generated for the primary cell. By making the primary cell large enough, the effect of spatial correlations introduced by the PBC on the structure and dynamics of the central solute may be minimized. Additionally, shaping the system into a space filling cell with PBC is a starting point for some more advanced simulation algorithms – constant pressure simulations, Ewald summation and the fast multipole method (FMM). The main disadvantage of explicit solvent simulations with PBC is the computational cost. The atoms included in nonbonded force calculations are those in the primary cell and a shell of image atoms on the surface, of the thickness equal to the cutoff distance. In typical solvated peptide/protein simulations, the solute, which is the focal point of our interest, makes up at most 10% of the system atoms. Since the nonbonded term calculations are the largest component of energy and force evaluation, this means that a majority of the computational time is spent computing solvent–solvent interactions. A number of approaches to overcome this difficulty have been proposed, as described below.

The simplest solution is to use a droplet or cluster solvent model, in which the solute is placed in a sphere of solvent. Adding a boundary potential enables control of system pressure and shape. Using this scheme a 3 ns simulation of the protein calmodulin was recently performed. The system included the 148 amino acid residues of calmodulin with four bound Ca\(^{2+}\) ions, 6 Cl\(^-\) and 22 Na\(^+\) ions in a water sphere of 44 Å radius. Significant reorganization of the protein structure compared to the starting X-ray structure was seen in the simulation, including deformation of the central helix and reorientation of the N- and C-terminal domains.

The stochastic boundary molecular dynamics (SBMD) method was originally proposed as a tool for performing cost-effective simulations of enzyme active sites. The starting point is a full protein, partitioned into a central region of interest (e.g. the active site), called the reaction zone, with the rest of the protein assigned to the reservoir region. The atoms in the reservoir region are either neglected or kept at fixed positions to generate a static background field. The reaction zone is solvated by introducing solvent molecules in to any available space, and is further divided into a central part – the reaction region and the surface layer – the buffer region. All atoms within the reaction region undergo standard Newtonian dynamics. Atoms in the buffer region experience forces due to the molecular potential energy function as well as some additional terms that compensate for the lack of external environment. To avoid major structural changes in the reaction zone, protein atoms in the buffer region are restrained to their initial positions by harmonic constraint potentials while solvent molecules are restrained to remain within a given distance of the center by a mean field spherical potential. To mimic the effect of collisions with molecules from the surroundings, all buffer atoms undergo Langevin dynamics, which includes a friction force and a random force. The surface constrained all-atom model is an approach similar in spirit to SBMD. The SBMD approach has been used to study local dynamics in several proteins, including ribonuclease A and hemoglobin. An illustration of a system set up for SBMD simulation is shown in Figure 6.

4.9.2 Langevin Dipoles–Protein Dipoles

Intermediate between explicit and continuum solvent models is the Langevin dipoles–protein dipoles model of Warshel. The solute is placed in a cavity inside a cubic grid of rotatable dipoles, with the grid spacing and average polarizability of the dipoles obtained from atomistic...
4.9.3 Continuum Models

In continuum models the solvent is treated as a bulk dielectric medium. The calculated quantities are related to the solvation free energy \( \Delta G_{\text{sol}} \), i.e. the free energy of transferring a molecule from the gas phase to dilute solution. \( \Delta G_{\text{sol}} \) is usually taken to be the sum of two terms as shown in Equation (46):\(^{128}\)

\[
\Delta G_{\text{sol}} = \Delta G_{\text{el}} + \Delta G_{\text{np}}
\]

\( \Delta G_{\text{el}} \) is the electrostatic contribution, which is the most important factor for polar or charged solutes in polar solvents, such as proteins and peptides in water. \( \Delta G_{\text{np}} \) describes van der Waals solute–solvent interactions, and reorganizing the solvent molecules to form the cavity which the solute occupies. The starting point of the electrostatic solvation free energy calculations are the Born formula, Equation (47), for a point charge \( q \):\(^{129}\)

\[
\Delta G_{\text{el}} = -\frac{q^2}{2a} \left( 1 - \frac{1}{\varepsilon} \right)
\]

and the Onsager formula, Equation (48), for the point dipole \( \mu \):\(^{130}\)

\[
\Delta G_{\text{el}} = -\frac{\varepsilon - 1}{(2\varepsilon + 1)a^3} \mu^2
\]

at the center of a spherical cavity in a medium of dielectric permittivity \( \varepsilon \). For more complicated charge distributions inside a spherical cavity the reaction field method of Kirkwood may be used.\(^{131}\) To treat molecules of arbitrary shape, two main methods are currently in use – the generalized Born (GB) and PB equations. In the GB method the solute atoms are assigned individual charges and radii. \( \Delta G_{\text{el}} \) is evaluated as the sum of Born-type and interaction terms.\(^{99,132}\)

In approaches using the PB equation, the system is represented as a low dielectric cavity (the solute) in a high dielectric medium (the solvent), including the presence of mobile ions.\(^{128,133}\) The PB equation shown in Equation (49)

\[
\nabla \cdot [\varepsilon(\vec{r}) \nabla \phi(\vec{r})] = \varepsilon(\vec{r}) \kappa^2(\vec{r}) \sinh[\phi(\vec{r})] = -4\pi \rho(\vec{r})
\]

determines the electrostatic potential \( \phi(\vec{r}) \) in the presence of a given spatial distribution of dielectrics \( \varepsilon(\vec{r}) \) and fixed charge density \( \rho(\vec{r}) \); \( \kappa^2 = 8\pi\varepsilon^2 N_A I / k_B T \) is determined by the ionic strength of the bulk solution \( I \), with \( \varepsilon \) the electronic charge, \( N_A \) Avogadro's number, \( k_B \) the Boltzmann constant and \( T \) the temperature. In PB calculations the solute atoms are assigned van der Waals radii and partial charges, both of which may be taken from model force fields or separately parameterized for this purpose.\(^{128}\) The atomic radii are used to define a contact surface between the solute and a probe solvent molecule.

Figure 6 (a) Intermolecular contacts in sickle-cell hemoglobin (HbS). Four HbS tetramers shown, each with two \( \alpha \) and two \( \beta \) chains, designated by different colors. Yellow and red spheres show sites of the sickle-cell mutation \( \beta 6 \text{Glu} \rightarrow \text{Val} \), located at the interface between two \( \beta \) strands. Blue and purple spheres show sites of \( \beta 121 \text{Glu} \rightarrow \text{Gln} \) mutation, located at interface of two hemoglobins within the same strand and responsible for aggravated sickling. (b) The simulation system for performing the mutation of the \( \beta 121 \text{Glu} \rightarrow \text{Gln} \) at the surface of an isolated hemoglobin. Structures from PDB file 1 HbS.\(^{126}\) (Adapted from K. Kuczera.\(^{127}\))

Simulations of the solvent being modeled (usually water), an iterative procedure is used to calculate self-consistent induced dipoles on the grid and on the solute ("protein") atoms, due to the electric field of the fixed solute charges and the other dipoles. The resulting solvation free energy captures the key features of the electrostatic term of solute–solvent interactions, while significantly reducing the computational cost.
Regions inside the surface are assigned a low dielectric permittivity (typically $\varepsilon \approx 2–4$), while outside $\varepsilon$ is set to the permittivity of the bulk solvent (e.g. $\approx 80$ for water). Numerical solutions of the PB equation give the potential $\Phi(\vec{r})$ and the electric field $\vec{E} = -\nabla \Phi$ on a grid in space. Visualizing the electric field with molecular graphics tools has yielded valuable information that is not evident from the protein structure alone.\(^{(128)}\) The calculation of electrostatic energies for macromolecules in different environments has allowed the prediction of changes of $pK_a$ values of ionizable groups in proteins, influence of salt concentration on nucleic acid conformations and ligand binding, and the electrostatic components of solvation free energies $\Delta G_{el}$.

Equation (50) shows that the nonpolar/cavity contribution to the solvation free energy is usually approximated by a term proportional to the total accessible area of the solute $A$\(^{(126)}\)

$$\Delta G_{np} = \gamma A + b$$  \hspace{1cm} (50)

where $b$ is a constant (usually small) and $\gamma$ is a microscopic surface tension term. Fitting the above expression to experimental data for small organic molecules gives $\gamma = 6 \text{cal mol}^{-1} \text{Å}^{-2}$ and $b = 0$ for vacuum to water transfer and $\gamma = 19 \text{cal mol}^{-1} \text{Å}^{-2}$ and $b = 0.6 \text{cal mol}^{-1}$ for cyclohexane to water transfer.\(^{(134)}\) Incorporation of continuum models into standard molecular modeling programs is currently under way.\(^{(135–137)}\)

An especially simple solvent model has been developed by Eisenberg and McLachlan.\(^{(136)}\) Equation (51) shows:

$$\Delta G_{sol} = \sum_{\text{atoms}, k} a_k S_k$$  \hspace{1cm} (51)

where $S_k$ are the solvent accessible surface areas of solute atoms and $a_k$ are parameters obtained by fitting to experimental data.

### 4.10 Treatment of Electrostatic Interactions

The electrostatic term in the potential energy describes interactions between the charge distributions on neighboring molecules. In the Born–Oppenheimer approximation, this molecular charge distribution is represented by point charges at the nuclei and a continuous function $\rho(\vec{r})$ giving the probability of finding an electron at point $\vec{r}$. Most current force fields use Equation (1) which expresses electrostatic energy in terms of interactions between point charges located at atoms. This approach involves several approximations. First, only charges are used in describing the molecular charge distribution, and higher multipole moments (dipoles, quadrupoles, . . .) are ignored.\(^{(99)}\) Second, the charges are assigned to atoms and are fixed, independent of conformation of the molecule or the nature of the surrounding environment. Third, the interaction is truncated at some cutoff distance to enable faster nonbonded calculations. The truncation at reasonable distances of 10 Å or higher does not greatly influence the van der Waals energy, which has terms varying as $1/R^6$ and $1/R^{12}$ and thus quickly decays to zero. However, the $1/R$ electrostatic interaction energy decays quite slowly; for two proton charges separated by 10 Å the energy is 33 kcal mol$^{-1}$, and even at 100 Å it is still significant at 3 kcal mol$^{-1}$.

Because of the presence of both nuclear charges and high electronic charge densities at the nuclei, it is natural and convenient to consider nuclei as centers for placing point charges. The disadvantage of such an approach is that it does not account for the asymmetric distribution of charge around atoms in molecules. Generalized schemes for placing charges off atomic nuclei have been proposed to study specific effects such as the structure of liquid water,\(^{(139)}\) aromatic–aromatic interactions\(^{(140)}\) or accurate modeling of hydrogen bonds.\(^{(111)}\) Distributed multipole analysis, in which charges, dipoles, quadrupoles, etc., are assigned to an arbitrary set of centers is a systematic approach to improved description of the details of molecular charge distributions.\(^{(114–117)}\) Such models suffer from technical difficulties in parameterization and energy/force calculation, and they have not been widely accepted. Attempts to include the effect of charge on molecular conformations have also been undertaken.\(^{(143–145)}\)

An important effect in condensed phases is polarization, which is described by the induction of an additional dipole moment $\mu_{ind}$ in a selected molecule by an external electric field $E$ generated by all the other molecules in the system,\(^{(84)}\) as shown in Equation (52):

$$\mu_{ind} = \alpha E$$  \hspace{1cm} (52)

where the coefficient $\alpha$ is the polarizability. In the most general case $\alpha$ is a tensor quantity. Due to polarization, the effective charge on a given atom will vary with environment. Introduction of polarization into molecular potentials leads to several difficulties – parameters describing polarizabilities have to be introduced and the simple pair-additivity of the potential is lost, because $E$ depends on positions of all atoms. Simple force fields usually include an average correction for polarizability. For example, the TIP3 water model\(^{(139)}\) has a dipole moment equal to the average molecular dipole moment in liquid water, which is about 15% larger than in vacuum. As a result, the average water–water interactions in liquid are correctly reproduced, but the energy of the water dimer in vacuum is exaggerated. Several potentials with explicit polarization have been introduced. The results indicate that for polar molecules and monovalent...
ions the polarization term is small, contributing 10–20% of the overall interaction energy and that the average correction approach should work acceptably. However for divalent ions, which generate higher electric fields in their vicinity, the polarization correction is expected to be significantly larger.

Even when the nonspherical distribution of charge around atoms, dependence of atomic charges on conformation, and polarization are taken into account, classical potentials still do not include the charge transfer effect, i.e. the fact that when molecules are brought together, electron density may flow from one molecule to another. In the final analysis, very high level quantum mechanical calculations have to be employed to correctly describe all aspects of nonbonded interactions.

Several approaches have been introduced to eliminate the need for the problematic truncation of electrostatic interactions. The whole class of continuum solvent models is discussed in section 4.9. Two powerful methods are discussed below – Ewald summation and fast multipole. The Ewald summation method is a natural extension of PBC simulations. An infinite crystal lattice is constructed from the primary simulation cell. A “neutralizing charge distribution” is introduced, which surrounds each atomic point charge by a diffuse charge distribution (usually a spherical Gaussian function) with the same total magnitude but opposite sign. The electrostatic interaction energy of the primary cell is split into two contributions – from the neutralized charges and from a second charge distribution, which cancels the first neutralizing charge distribution. The first term converges quickly with distance, and is evaluated by a direct sum over neighboring atoms within a cutoff distance. The second term converges slowly in reciprocal space and is evaluated by a direct sum over neighboring atoms within a cutoff distance. The disadvantage of the Ewald method is that it breaks the minimum image convention and tends to reinforce artifacts due to the PBC Ewald method is that it breaks the minimum image approximation, and polarization are taken into account, classical potentials still do not include the charge transfer effect, i.e. the fact that when molecules are brought together, electron density may flow from one molecule to another. In the final analysis, very high level quantum mechanical calculations have to be employed to correctly describe all aspects of nonbonded interactions.

An alternative approach to summing up long-range interactions is the FMM. In FMM space is divided into cubic cells, and multipole moments are calculated for each cell. While normal atomic pairwise summation is used at closer distances, the interaction energies of particles which are more than one cell away are evaluated using local Taylor expansions of the multipole potentials. Grouping together neighboring cells is employed to further speed up calculations.

The PME and FMM method become quite efficient for large systems. The cost of direct summation of pairwise interactions scales like $O(N^2)$ with the number of atoms, since there are $N(N-1)/2$ distinct pairs. In cutoff-based methods each particle interacts with some fixed average number of other particles within the cutoff radius and the scaling is $O(N)$. With the PME algorithm, the cost is $O(N \ln N)$, while with the periodic version of FMM it is only $O(N)$. It is expected that starting at $N \approx 20000$ the periodic FMM method will be the most cost effective and accurate way to evaluate long-range interactions.

4.11 Path Exploration Methods

Modeling of structural transitions in large molecular systems encounters two types of difficulties. First is the problem of timescale, as large scale structural changes occur over periods of time longer than those accessible to current direct simulations. Second, while the end-points of the transition (initial and final state) may be known (e.g. crystal structures of oxy- and deoxyhemoglobin), the details of the reaction path are often unclear. In many cases the reaction coordinate involves hundreds or thousands of atoms, leading to the need for specific new methods of path exploration. Approaches to efficiently describe such transitions include the self-penalty walk (SPW), locally updated planes (LUP) and conjugate peak refinement (CPR). All these methods consider a straight line connecting the initial and final state as a starting approximation to the reaction coordinate, and proceed to refine a numerical description of this coordinate by optimizing structures of intermediate states. In the SPW method $M$ copies of the system are considered, initially in an equally spaced arrangement along the straight line connecting the initial and final state in Cartesian space. The potential energy of this “supersystem” is taken as the sum of the (standard) molecular potential energies of the individual copies and two penalty terms depending on the distance between copies. The penalty terms are a harmonic contribution due to deviation of the nearest-neighbor distance from the average and a Gaussian repulsive contribution between copies. Energy minimization of this “supersystem” leads to an optimized continuous path connecting the initial and final state, with the intermediate structures approximately equally spaced. In the LUP again a “necklace” or “polymer” of equally spaced intermediate structures is the starting point. These structures are refined by constrained optimization in the direction orthogonal to the local reaction coordinate. This method is quite simple to implement and efficient due to the use of linear Cartesian constraints. In the CPR method alternate searches along the reaction coordinate and in the orthogonal direction...
allow the identification of one or more transition states and/or intermediate minima between a given initial and final point.\(^{150}\)

4.11.1 Applications

The LUP approach has been employed to determine the path for the transition between the \(\alpha\)-helix and \(3_{10}\)-helix in short model peptides\(^{151}\) (see Figure 1). The sequential transition, in which residues change conformation one at a time was found to have a barrier of 2 kcal mol\(^{-1}\).\(^{151}\) A combination of LES and SPW methods was employed to study ligand escape in the protein leghemoglobin.\(^{152}\) Leghemoglobin is an oxygen binding protein from plants, analogous to myoglobin in vertebrates. The reactive oxygen ligand is tightly bound to an iron atom of a heme, which is sequestered inside the protein, with no evident path of escape in the crystal structure. Using LES, a swarm of noninteracting ligands was first used to obtain a statistical picture of the pathways of ligand escape. Based on the generated ligand distribution, three somewhat different exit paths were proposed, and potentials of mean force along them were evaluated using the SPW. Two general properties of the ligand exit paths were: an initial activated step with a barrier of 2.5 kcal mol\(^{-1}\), involving local motions of the ligand and sidechains of Phe 29 and Phe 44 lining the binding pocket; and a barrierless, diffusive step involving displacement of the G helix, with hundreds of atoms displaced along the reaction coordinate.

5 RELATION TO EXPERIMENTAL APPROACHES

A number of peptide and protein properties are accessible to both modeling and experimental studies. Verification that the calculated property values agree with measured data is an important test of the quality of modeling techniques. On the other hand, microscopic explanation of the observations is the goal of all modeling studies. Thus, availability of both sorts of information is highly desirable for complex molecular systems. Relationships between some fundamental calculated and observed quantities are outlined below. An excellent, in-depth discussion of this topic is given in Brooks et al.\(^{61}\)

5.1 X-ray Diffraction

X-ray diffraction experiments are most often the source of structural data for starting macromolecular simulations. In many cases, the diffraction experiments also yield the Debye–Waller factors (isotropic temperature factors).

For a given atom \(i\) the relationship between the temperature factor \(B_i\) and the mean-square position fluctuation is (Equation 53):\(^{61}\)

\[
\langle \Delta r^2 \rangle = \frac{3}{8\pi^2} B_i
\]  

(53)

Thus, accuracy of MD motional amplitudes may be tested by comparing calculated atomic fluctuations with the temperature factors. Some care has to be taken in the comparison due to the presence of a static disorder contribution in the X-ray data.\(^{153}\)

Combining the information content of a molecular force field and the X-ray diffraction pattern has led to the development of an improved X-ray structure refinement protocol.\(^{154}\) In this approach, the refinement residual, i.e. the difference between the observed and calculated structure factors \(F_{hkl}\), is added to the molecular potential \(U(q)\) as a penalty function, or constraint. In “low energy” regions of the combined potential the geometry and interatomic contacts are reasonable while the structures correspond to low values of the crystallographic \(R\)-factor. In combination with simulated annealing or elevated temperature MD, use of such potentials is a powerful tool in the final stages of X-ray structure refinement, used e.g. in the popular program XPLOR. A comparison of observed and measured atomic fluctuation amplitudes for myoglobin is given in Figure 7.\(^{90,155–158}\)

### Figure 7

Myoglobin atom fluctuations: MD vs experiment. Root mean square position fluctuations averaged over all non-exchangeable hydrogens: from 50 ps vacuum MD trajectories of myoglobin bound with CO (circles) and from incoherent neutron scattering (squares).\(^{90,155,156}\) Triangles: average over backbone atom root mean square position fluctuations calculated from X-ray Debye–Waller factors.\(^{157}\) (Adapted from K. Kuczera.)\(^{158}\)
5.2 Nuclear Magnetic Resonance Spectroscopy

The measured NMR vicinal coupling constants $^3J_{HH}$ are used to determine the dihedral angle $\theta$ formed by the atoms involved through the Karplus equation shown in Equation (54):

$$^3J_{HH} = A \cos^2 \theta - B \cos \theta + C \quad (54)$$

where $A$, $B$ and $C$ are parameters determined from model studies. The trajectory values of the dihedral $\theta(t)$ may be used to predict an average value and fluctuations of the dihedral and of the $^3J_{HH}$ function given above. Such calculations can test the similarity of families of conformations sampled in simulations and in experiments.

Nuclear Overhauser effect (NOE) experiments are sensitive to the distance between atoms. NOE results may be compared to simulation averages of $(r_{ij}^{-6})$, where $r_{ij}$ is the distance between atoms $i$ and $j$.\(^{(159)}\) In the process of structure determination from NOE data, a penalty function $U_{NOE}$ is defined by Equation (55):

$$U_{NOE} = \sum_k A_k (R_k - R_{NOE,k})^2 \quad (55)$$

where $k$ numbers atom pairs, and $R_k$ and $R_{NOE,k}$ are the current and NOE determined distance between atoms in the pair, respectively. The coefficients $A_k$ are used to weight the NOE penalty function $U_{NOE}$ relative to the molecular potential $U(q)$. Simulations for crambin, a small protein of 46 residues, showed that inclusion of NOE interproton distance information enables simulating a transition from a fully extended polypeptide chain to the correctly folded structure on timescales of tens of picoseconds.\(^{(160)}\)

Order parameters $S^2$ have been used to extract the information on internal motions of biomolecules from NMR measurements.\(^{(161)}\) An order parameter measures the degree of spatial restriction of the motion of a vector and is defined model-independently as Equation (56):\(^{(161)}\)

$$S^2 = \lim_{t \to \infty} C_r(t) = \frac{4\pi}{5} \sum_{m=-2}^2 |\langle Y_{2m}(\theta, \phi) \rangle|^2 \quad (56)$$

where $C_r(t)$ is the correlation function describing internal motion and the $Y_{2m}$ are the second-order spherical harmonics as functions of the angular spherical coordinates $\theta$ and $\phi$ of a vector between two atoms in the molecule-fixed frame. Calculating order parameters from an MD trajectory provides a way to obtain information about internal motions i.e. directly comparable to experimental data.\(^{(161)}\)

5.3 Hydrogen Isotope Exchange

Experiments involving exchange of amide NH protons with deuterium from solvent provide direct evidence for protein internal motions and can be used to study pathways of protein folding.\(^{(162)}\) Exchange rates for NH protons in native proteins span a wide range of values, and are up to $10^6$ slower than in small molecules where the protons are exposed to solvent. As longer simulations of solvated proteins are performed, it is expected that structural fluctuations exposing buried protons to solvent will be observed. This will help resolve the controversy about the microscopic mechanism of the exchange.\(^{(163)}\)

5.4 Fluorescence Depolarization

Fluorescence depolarization measurements can probe internal motions of peptides and proteins by following the reorientation of fluorescent labels, such as aromatic residues.\(^{(164)}\) For the case of parallel absorption and emission dipoles the fluorescence anisotropy decay is given by Equation (57):\(^{(165)}\)

$$r(t) = \frac{I_1(t) - I_L(t)}{I_1(t) + 2I_L(t)} = \frac{2}{3} C_2(t) \quad (57)$$

where $I_1$ and $I_L$ are the intensities of emitted light with polarization parallel and perpendicular to that of the exciting pulse and $C_2(t)$ is the correlation function of the emission dipole, as shown in Equation (58):

$$C_2(t) = \frac{(3\cos^2(\theta) - 1)}{2} \quad (58)$$

where $\theta(t)$ is the angle of rotation of the emission/absorption dipole during time $t$. Similar relations may be obtained for linear dichroism and transient absorption measurements.\(^{(166)}\)

For a system undergoing simple rotational diffusion, it is expected that the principal axes of the rotational diffusion tensor will reorient according to Equation (59):\(^{(165,166)}\)

$$C_{2,i}(t) = a_i e^{-(6D_i + 2 \Delta \lambda t)} + b_i e^{-(6D_i - 2 \Delta \lambda t)} \quad i = x, y, z \quad (59)$$

where $a_i$, $b_i$ are weights that depend on the diffusion coefficients around the individual axes, $D_x, D_y, D_z$; $D_r = (D_x + D_y + D_z)/3$ is the average rotational diffusion coefficient; and $\Delta \lambda$ is a measure of anisotropy. Fitting the $C_{2,i}(t)$ functions to exponential decays can provide information on timescales of molecular reorientation. Results of simulations and experimental measurements may thus be compared. The comparison becomes more difficult in the case of asymmetric chromophores, where up to five different exponents are expected in $C_{2,i}$.\(^{(166)}\) and in the case when the motion may have several components, e.g. for a tryptophan in a protein, where overall protein tumbling and local sidechain reorientations may be differentiated.\(^{(6)}\) Recently, some interesting and unexpected results have been obtained in simulations of simple
aromatic fluorophores in solution. Significant effects of microscopic solvent packing and interactions on rotational diffusion around individual molecular axes were found.\(^{187}\) Extending such studies to peptide and protein systems could greatly enhance the amount of information that can be extracted from fluorescence depolarization studies.

5.5 Vibrational Spectroscopy

Vibrational spectroscopy of peptides and proteins provides information on the frequencies of molecular vibrations. This information is used in various ways. Infrared and Raman spectroscopy are most often used to study the relatively high frequency, localized motions of the amide groups. These frequencies are highly sensitive to the environment, and can be used to characterize protein secondary structure.\(^{168,169}\) Specific isotope labeling and isotopic frequency shifts are employed to dissect enzymatic reaction mechanisms.\(^{170}\) Resonance Raman spectroscopy is employed to analyze structure and interactions of chromophoric prosthetic groups.\(^{171}\) As described in section 4.4, the model potentials used for peptide and protein simulations give a rather approximate picture of the high frequency localized group motions. However, normal mode analysis is highly useful in providing models for the low frequency delocalized motions which cannot otherwise be assigned.\(^{69}\)

5.6 Neutron Scattering

In incoherent inelastic neutron scattering, the intensity of neutrons scattered from a sample is measured as a function of energy and momentum transfer. This yields information about the amplitudes and timescales of hydrogen atom motions.\(^{172}\) Average hydrogen positional fluctuations can be determined from neutron scattering experiments and directly compared with simulation results (see Figure 7 for an example). Atomic motions from MD trajectories may be used to generate simulated incoherent neutron scattering profiles which are in excellent agreement with experimental observations. Additionally, based on the simulations, types of molecular motions that are responsible for different features of the observed neutron spectra may be determined.\(^{172}\)

6 EXAMPLES OF APPLICATIONS

MD simulations of a wide range of peptide and protein properties have been reported. Protein simulations started with vacuum trajectories, focusing on calculation of atomic fluctuation amplitudes of small globular proteins: BPTI,\(^{19}\) myoglobin\(^{20}\) and lysozyme.\(^{173,174}\) These studies showed qualitative agreement with X-ray temperature factors, but also found that atomic fluctuations in proteins tend to be highly anisotropic and anharmonic. For lysozyme, a change in the pattern in atomic mobility between the free and liganded forms of the enzyme was found, consistent with the observed greater rigidity of the liganded form.\(^{173}\) Analysis of timescales of sidechain motions in MD trajectories indicated that folded globular proteins exhibit an unexpected mobility – even over picosecond timescales rotations of Tyr groups by up to 30° were found.\(^{175}\) Calculations of dielectric relaxation, translational diffusion and rotational diffusion of BPTI and lysozyme showed good agreement with experimental data,\(^{176}\) with dielectric relaxation and rotational diffusion occurring on the nanosecond timescale. A recent 1 µs simulation of a 38-residue peptide from the vilin headpiece subdomain in 3000 waters progressed from the totally unfolded structure to a collapsed compact form with formed α-helices and favorable solvation free energy. However, the final conformation of the peptide still exhibited some significant deviations from the folded structure.\(^{40}\) Thus, protein folding still falls outside the timescales accessible to atomistic simulations. Several studies have approached the reverse process of protein unfolding by changing the temperature, solvent composition, perturbing structure or making a point mutation.\(^{38,177}\) The general conclusions from these simulations are that unfolding is due to a change in the balance between protein–protein and protein–solvent interactions. The details of the unfolding and the final state reached vary when different methods of initiating unfolding are used.

A number of studies have gone beyond answering basic physical questions to modeling aspects of protein function. Early work focused on the protein myoglobin, which may be considered a model for understanding relations between biological function and protein motions. Two types of motion occur in myoglobin – equilibrium fluctuations and nonequilibrium relaxation.\(^{178}\) The structural fluctuations are necessary for exit of small ligands (O\(_2\), CO, NO, etc.) from the heme binding site to external environment. The relaxation is the directional structural transition upon ligand dissociation from the heme, involving motion of the iron atom out of the heme plane and subsequent tertiary structure change (see Figure 8\(^{15,158,179}\)). Studies of ligand escape pathways included suggestion of an intuitive simple path obtained by minimal distortion of the protein structure through rotation of two surface sidechains.\(^{61}\) The energetics of this pathway were explored using adiabatic mapping\(^{180}\) and umbrella sampling,\(^{119}\) suggesting that it should be accessible due to thermal fluctuations. Further simulations employing the LES approach suggested existence of several alternative exit pathways for ligands
Figure 8 Fe atom displacement of the heme in myoglobin upon CO dissociation. Also shown is proximal histidine 93. (a) Six-liganded planar heme (Adapted from K. Kuczera). (b) Five-liganded domed heme. (Adapted from K. Kuczera)

from the myoglobin interior, some involving extended ligand diffusion through the protein matrix. Protein structural relaxation after ligand dissociation were simulated by initiating either a sudden potential parameter change or injection of kinetic energy into the heme. These studies found a complex, nonexponential behavior. The simulated time course of the iron atom out-of-plane displacement agreed with time resolved infrared measurements and was used to explain why the observed rebinding for NO is nonexponential, while for CO or O₂ it is exponential at room temperature. Simulations of the actual rebinding process did not find significant long-term structural relaxations, but suggested that non-exponential recombination may be explained by ligand diffusion through the protein. An extended discussion of this still controversial question may be found in Kuczera.

The structure and function of RNase A were investigated in Haydock et al. For this protein the X-ray structure of the enzyme–inhibitor complex was inconsistent with biochemical and mechanistic data on the reaction. Using the SBMD approach to model the active site and its surroundings, the actual substrate was built in place of the inhibitor in a crystal structure. After energy minimization and a short period of MD, the sidechains in the active site rearranged in a manner consistent with experimental aspects of the reaction mechanisms. This application clearly demonstrated the flexibility and utility of modeling methods. Several studies focused on motions of “flaps” or “lids” which open to allow entry of substrate into the active site and then close to sequester the substrate in a nonaqueous environment. For triosephosphate isomerase, static analysis of the “open” and “closed” conformations from X-ray crystallography was supplemented by high-temperature MD simulations to show a possible transition pathway. Analogous simulations for lactate dehydrogenase led to identification of the loop hinges from cross-correlations of atomic displacements. In the case of human immunodeficiency virus (HIV) protease, simulations in water showed significant rearrangement of the enzyme flaps (which sequester the active site from solvent) compared to the crystal structure, where the flaps are involved in crystal contacts (see Figure 9). The proposed solution structure of the free enzyme corresponded to a more closed flap state than expected.

Molecular modeling of peptides has been progressing along two main paths – detailed simulations of small model peptides aimed at developing new methods and building basic understanding, and approximate studies of larger systems targeted at practical structure prediction of biologically active molecules. A number of examples of practical applications involving peptide-based drug design have been described. The procedure starts conformational analysis of a biologically active peptide such as bradykinin (9 residues), angiotensin (8 residues) or substance P (11 residues) with highly simplified interactions with the environment (vacuum or constant
dielectric treatment). A rough grid search, build-up procedure or simulated annealing are used to obtain a set of low energy conformers, representing several possible structures. These structures are then used to design constrained analogs of the parent compounds. The activity of the analogs is assayed, providing information about the putative structure of the biologically active parents, about the receptors as well as development of compounds with improved potency, selectivity and stability.

More advanced methods are typically used for fundamental simulations of simpler systems. Force fields for peptides and proteins are usually calibrated on predictions of relative conformational energies of the "alanine dipeptide" (α-(formylamino)propanamide) (Figure 4). Nanosecond length simulations in explicit solvent have been performed for a series of short peptides. In several simple cases such as (Ala)₃, (Val)₃ or Tyr-Pro-Gly-Asp-Val, complete conformational sampling was achieved in several nanoseconds, as the same set of structures was visited several times, allowing the calculation of equilibrium constants directly from trajectories.

The role of salt in the simulations of solvated biomolecules has been studied, including the distribution of counterions, influence on conformational equilibria and dynamics. Comparative simulations of cyclic (disulfide bridged) and linear versions of the RGD peptide Ac-Pen-Arg-Gly-Asp-Cys-NH₂ (Pen – penicillamine) and opioid peptide DPDPE were used to quantify the effects of disulfide constraints. Using several different measures, rates of conformational exploration of the linear forms were about two to three times faster than those of the cyclic ones. The free energy cost of restricting the linear peptide to the conformations available to the cyclic form was estimated at 4–6 kcal mol⁻¹. A number of studies have approached the problem of unfolding and initiation of peptide α-helices in water. A complex overall picture was found, with partial unfolding proceeding from the C-terminus toward the N-terminus on a nanosecond timescale, and transient population of alternative helix forms. Recent simulations indicate that helix initiation is associated with a barrier of ca. 3 kcal mol⁻¹, corresponding to a rate of 0.1–0.01 ps⁻¹, faster that previously expected, and that the complete helix formation from a disordered structure should occur within 20–70 ns at room temperature. These timescales are much longer than used in many previous simulations, but are quickly coming within reach of current computational studies.

Recently, β-peptides, a class of peptide analogs with an additional carbon atom in the backbone, have attracted significant attention. β-peptides have the same functional groups as regular peptides, exhibit a tendency to form regular secondary structures, and are resistant to degradation by proteases. These molecules are thus a promising source of potential biologically active agents. They are also good targets for simulations, as relatively small systems are capable of forming regular structures. MD simulations of a seven residue β-peptide in aqueous solution at several temperatures on 50 ns timescales generated an equilibrium distribution of conformers. The β-peptide repeatedly visited a relatively small number of conformations (≥10⁴), with the experimentally observed left-handed 3₁ helix being predominantly populated (Figure 10). Free energy differences between conformers, the melting temperature and folding free energy were determined from the trajectory. Multiple pathways to the folded state were found.

Early free energy simulations of peptide/protein systems involved successful calculations of solvation free energy differences between sidechain models. Further studies used the idea of thermodynamic cycles to study influence of protein point mutations on thermal stability of T4 lysozyme, cooperative oxygen binding to hemoglobin and the hemoglobin sickling aggregation. In all these studies the calculated overall free energy change was in qualitative agreement with experimental results. Additionally, interesting and unexpected effects were found in analysis of the detailed simulation results, supplying valuable insight into the observed effects. The hemoglobin studies found effects of removal of favorable interactions as well as the creation of favorable ones, differential solvation of wild type and mutant structures, and nonobvious contributions from individual residues to the overall process.
example of a challenging and interesting application are the free energy simulations of binding of biotin and the protein streptavidin.\textsuperscript{111} This is probably the strongest known protein–organic ligand interaction, with a binding free energy $\Delta G_{\text{assoc}}$ of $-18$ kcal mol$^{-1}$. The simulations were able to correctly predict the relative binding free energies of biotin, thiobiotin and iminobiotin, and also to determine the absolute free energy of biotin binding.\textsuperscript{111}

An interesting conclusion from the calculations is that the unusual stability of the biotin–streptavidin complex is due to van der Waals/hydrophobic type energy terms, rather than electrostatic. This is because the charged and polar groups involved in binding tend to interact equally well with each other in the bound state as with water in the uncomplexed state.

The system size and complexity. Current simulations involve systems of $10^3$–$10^4$ atoms; within the next 5–10 years sizes of $10^4$–$10^5$ atoms will become standard. The systems themselves, from the current solvated peptides, proteins or nucleic acids, will become more complex, including buffer ions and interfacial environments. This will enable studies of many new interesting biochemical systems, including large, multisubunit proteins, proteins in membranes and protein–nucleic acid interactions.

Simulation length. The standard of simulation length is changing from 100 ps several years ago to about 1–5 ns currently. This trend will certainly continue and longer simulations can be expected in the future. With longer simulations, structural and energetic dynamics will be probed on longer timescales. This will also provide larger samples of configurations and yield more accurate averages. Parallel computing will be used to extend both system size and simulation length. Improved algorithms involving symplectic, reversible, splitting and stochastic approaches will be more widely implemented.

Potentials. More accurate potential energy functions are being developed. Improvements include both description of internal structural deformations and nonbonded interactions. In the internal deformation force field off-diagonal, anharmonic and conformation-dependent terms are being added. More accurate representations of the static charge distribution, inclusion of polarization and avoidance of truncation effects will become widespread in electrostatic energy calculations. At the level of van der Waals interactions, nonadditive corrections are being introduced to improve agreement with experimental data.\textsuperscript{111} Mixed QM/MM approaches will be more widely used, which allow the quantum mechanical
MOLECULAR MODELING IN PEPTIDE AND PROTEIN ANALYSIS

Figure 11 Two-dimensional conformational free energy maps of (Ala)$_{10}$ and (Aib)$_{10}$ in vacuum. Aib is α-methylalanine. (a) Map of free energy gradient for (Ala)$_{10}$ showing two minima, corresponding to the α- and π-helices. (b) Map of free energy gradient for (Aib)$_{10}$ showing two minima, corresponding to the α- and 3₁₀-helices. (c) Free energy surface corresponding to (a). (d) Free energy surface corresponding to (b). (Adapted from Y. Wang, K. Kuczera.)

- Sampling. Enhanced sampling algorithms are becoming part of standard tools of molecular modeling. These include approaches such as LES, path exploration algorithms, and other approaches such as essential dynamics (based on singular value decomposition) or self-guided dynamics (based on potential energy smoothing). In the field of free energy simulations soft-sphere potentials are being considered as tools for accelerating convergence of the statistical mechanical averages.

- Simplified models. The revolution in molecular biology is generating ever increasing numbers of protein sequences and information about interactions between macromolecules with each other and with small effectors. This is driving the growing use of simplified approaches which are able to yield quick though approximate results. The treatment of solvation through the PB and GB methods described in section 4.9 belong in this class. Another class of methods decreases the number of interaction centers through the use of coarse-grained models. Comparative modeling aims to predict protein structures based on known three-dimensional structures of proteins with similar sequences. Docking methods that predict binding of small ligands to macromolecules using simplified interaction potentials are of growing importance for drug design. Another class of interesting approaches are lattice methods, which are generating highly useful insights into protein folding.

ACKNOWLEDGMENTS

I would like to thank Dr Gouri Jas, Mr Robert Guenther and Mrs Terrie Saunders for help with preparing the
figures for this article. The molecular graphics were prepared using MolScript\textsuperscript{214} and Raster3D.\textsuperscript{215,216}

MOLECULAR MODELING IN PEPTIDE AND PROTEIN ANALYSIS

MOLECULAR MODELING IN PEPTIDE AND PROTEIN ANALYSIS

Peptide Diastereomers, Separation of

Gerhard K.E. Scriba
University of Jena, Jena, Germany

1 Introduction

The separation and identification of optical isomers of synthetic or naturally occurring peptides is of great importance. Diastereomeric peptides, isomers in which one or more of the chiral centers have been converted to the opposite configuration, (R) or (S), often possess different biological activities and/or conformational properties. Therefore, the separation and determination of diastereomeric peptides is particularly significant to the pharmaceutical industry for quality control of peptide synthesis and stability as well as for regulatory requirements.

Diastereomers are stereoisomers that are not related as mirror images, whereas epimers are defined as diastereomers differing in the configuration of only one chiral center. Diastereomers differ in their physicochemical properties and often possess different conformations. They can be determined by many techniques such as crystallization, enzymatic reactions, optical rotation, circular dichroism, differential scanning calorimetry, IR spectroscopy, NMR spectroscopy, mass spectrometry (MS), as well as chromatographic and capillary electrophoretic separation methods. Although it is generally possible to distinguish between diastereomers with all techniques mentioned, only chromatography and CE allow the simultaneous separation, identification and determination of even complex mixtures of diastereomers. Epimeric impurities well below 1% can be detected and quantified.

Applications of the analysis of peptide diastereomers include the indirect determination of the optical purity of amino acids, the detection of epimerization of amino acid residues during peptide synthesis and degradation, and the direct determination of the optical purity of peptides. Although systematic studies have been performed primarily with di- and tripeptides, specific procedures have been developed for certain compounds or closely related analogs.

This article covers analytical-scale separations of peptide diastereomers by chromatographic and electrophoretic techniques. Preparative procedures are not discussed. The article also focuses on peptides containing naturally occurring amino acids, although some analogs...
are listed in a few cases. Diastereomeric diketopiperazines derived from dipeptides are included. A review on the chromatographic separation of peptides containing β-alkyl amino acids has been published recently by Peter and Toth.(3)

2 CHROMATOGRAPHIC SEPARATIONS

Chromatographic separations of diastereomeric peptides have been reported by PC, TLC, GC and HPLC. No peptide diastereomer resolution by supercritical fluid chromatography (SFC) has been published. This may be due to the low solubility of native peptides in supercritical carbon dioxide. Today, HPLC is the most common technique for the resolution of peptide diastereomers.

Separation mechanisms in chromatography include adsorption and/or distribution between the stationary phase and the mobile phase as well as ion exchange phenomena. Differences in the adsorption/distribution characteristics between diastereomers result in their separation.

With a few exceptions in which resolutions of diastereomeric peptides were performed using chiral stationary phases or chiral additives, most published separations were achieved using achiral stationary phases. Although it is generally possible to separate diastereomers on chiral phases, this topic is not covered in the article. Chiral stationary phases and separation methods are treated in monographs on chiral chromatographic separations(4–6) as well as in the relevant articles of this encyclopedia – Gas Chromatography: Introduction; Column Technology in Gas Chromatography; Liquid Chromatography: Introduction; Column Theory and Resolution in Liquid Chromatography; Normal-phase Liquid Chromatography; Reversed Phase Liquid Chromatography and Thin-layer Chromatography.

2.1 Paper Chromatography

The first separation of the diastereomers of a dipeptide was reported in 1950 by PC.(7) Since then numerous di- and tripeptides have been separated primarily on Whatman® No. 1 paper by ascending or descending techniques (Table 1). The peptides were detected employing the ninhydrin reaction. Although most early reports used acidic solvent systems,(7–11) many basic solvent mixtures have been applied even more successfully in subsequent work.(9–14) Generally, dipeptides are resolved more efficiently than tripeptides. Higher Rf values were found for the LL/DD diastereomeric pairs of dipeptides compared to the DL/LD epimers. A diastereomeric hexapeptide has also been resolved, the LDLLLL epimer displaying a higher Rf value than the LLLLLL isomer.(11) The diastereomers

of Leu dipeptides have been separated by ion-exchange PC using Amberlite® SA-II paper in its ammonium form.²⁴

### 2.2 Thin-layer Chromatography

Separations of diastereomeric di- and tripeptides as free³⁴ or protected derivatives³⁵–³⁷ by TLC have been achieved using cellulose,³⁵ silica gel,³⁵,³⁶,³⁷ reversed-phase (RP) materials,³⁸ and RP phases impregnated with cationic or anionic detergents³⁹ or ammonium tungstophosphate (AWP)-coated plates⁴⁰ as stationary phases (Table 2). With a few exceptions acidic solvent systems have been employed. Higher \( R_f \) values were observed for the LL/DD diastereomeric pairs of free dipeptides compared to the corresponding LD/DL epimers on cellulose,³⁵ silica gel,³⁵,³⁶ and RP materials.³⁸ In contrast, AWP as adsorbent retained the LL/DD epimers more strongly than the LD/LD diastereomers, resulting in a reversal of the \( R_f \) sequence.³⁸

²⁵ Optimized conditions.

²⁶ Higher \( R_f \) value listed first.

²⁷ ONP, o-Nitrophenoxy ester.
detergent-impregnated RP materials depended on the type of detergent used. Thus, the LL/DD pair displayed higher \( R_f \) values than the LD/DL pair when the anionic detergent HDBS was used in combination with acetic solvent mixtures, whereas the retention order was reversed for the cationic detergent N-DPC and for basic mobile phases.\(^{(16)}\) The retention order of protected dipeptides strongly depended on the type of derivatization of the N- or C-terminus.\(^{(17)}\) The all-L stereoisomer of the tripeptide Ala-Ala-Ala was less retained than the mixed epimers with L-L-D or L-D-L configuration on RP/TLC plates and RP materials coated with an anionic detergent, whereas the L-L-L isomer was retained more strongly than the L-D-L epimer on AWP-coated TLC plates.\(^{(16)}\)

The resolution of free dipeptides by ligand exchange on chiral stationary phases has been reported.\(^{(21,22)}\) The DL isomers were less retained than the LL isomers of all dipeptides investigated.

Diketopiperazines derived from diastereomeric dipeptides could also be resolved on silica gel plates using acetic solvent mixtures\(^{(26–28)}\) (Table 3). The DL epimers with trans-substituted piperazine-2,5-dione moiety displayed higher \( R_f \) values than the LL isomers with cis conformation of the substituents.

2.3 Gas Chromatography

The separation of peptides by GC generally requires the derivatization of the amino and the carboxyl group. N-Acyl-peptide esters have been primarily investigated. Only one report described trimethylsilylation for derivatization. The majority of analyses have been performed on packed columns. Various stationary phases have been investigated. Weygand et al.\(^{(29)}\) first succeeded in separating the diastereomers of Ala-Phe as the N-trifluoroacetyl (N-TFA) methyl ester. Later the same group reported the resolution of many N-TFA dipeptide methyl esters.\(^{(30)}\) Except for Ala-Ala, the DL epimers were retained stronger than the LL isomers. The trimethylsilyl (TMS) derivatives of dipeptides could be resolved on a 12-m SE-54 fused-silica capillary column.\(^{(31)}\) The LL/DD isomers had shorter retention times than the LD/DL isomers.

The separation of N-TFA and N-tetrafluoropropionyl (N-TFP) tetrapeptides obtained by reaction of N-TFA propyl and N-TFP-propyl derivatizing reagents and tripeptide methyl esters using packed columns were described, the LDL/L epimers eluting first (Table 4).\(^{(32,33)}\)

Diastereomeric diketopiperazines can also be resolved by GC using several stationary phases\(^{(28,37)}\) (Table 5).

ethanol. In some cases alkylsulfonates as ion-pair reagents or metal ions were added. Ion-exchange chromatography was sometimes applied successfully. Dipeptides, neurotensin, or angiotensins were resolved on weak anion exchange columns while cation exchange packings were used for gramicidin analogs and hGRF. Few reports on normal-phase HPLC for the resolution of diastereomeric N-derivatized di-, tri-, and tetrapeptide esters using mixtures of organic solvents as eluents have been published.

With a few exceptions the LL epimers of dipeptides were resolved faster than the LD diastereomers on RP or anion exchange columns, regardless of whether the peptides were analyzed as free peptides or as N-derivatives. This behavior is attributed to the spatial arrangement of the side chains of the amino acid residues leading to different hydrophobicities of the diastereomers. In the LD or DL forms the side chains are on the same side of the peptide bond and in close proximity to one another. This results in a higher overall hydrophobic surface area and in increased retention compared to the LL and DD forms where the side chains are on opposite sides. The all-L epimer of tripeptides eluted faster in most cases than the mixed epimers. As the size of the peptides increases, further factors contribute to the overall hydrophobicity so that the retention behavior of the peptide diastereomers becomes less predictable. The retention order of the diastereomers of N-derivatized dipeptide esters depended on the type of the derivative. Table 6 summarizes separations of diastereomeric peptides ranging from dipeptides to peptides containing 44 amino acids.

The HPLC technique can also be applied to the separation of diketopiperazines derived from diastereomeric dipeptides. Examples are summarized in Table 7.

#### 2.5 Method Development

Method development will be only addressed briefly for HPLC as this is the most important chromatographic technique for peptide diastereomer separations. In the RP mode ODS (C-18) columns have been most frequently used. However, the packing material from various manufacturers may differ with respect to carbon loading, endcapping of residual silanol groups, etc. The separation of peptide diastereomers is particularly sensitive to differences in the composition of the stationary phase. Moreover, the individual should be aware of the mechanism that dictates the selectivity for an HPLC separation.

In most RP analyses low-pH aqueous solvents should be employed – TFA is probably most versatile but sodium phosphate, TEAP, ammonium acetate, or TEAA is also very suitable. The ionic strength of the buffer can also be crucial for a successful separation. Following optimization of the pH and the type and the concentration of the organic modifier, additives such as ion-pair reagents or metal ions can be tested.

In cation-exchange chromatography TFA/acetonitrile mixtures are most frequently used ensuring protonation of the carboxylic acid groups of the peptides. In anion-exchange HPLC solvent systems with higher pH values have been employed.

### 3 ELECTROPHORETIC SEPARATIONS

Electrophoretic methods comprise several techniques including paper electrophoresis, gel electrophoresis, and CE. Despite the fact that the resolution of the diastereomers of the dipeptides Lys-Glu and Lys-Asp by paper electrophoresis has been reported, virtually all separations of diastereomeric peptides have been carried out by CE in recent years. Due to its extremely high resolution ability, CE has become a powerful tool for the analysis of polar compounds such as peptides.

The separation mechanism of electrophoretic techniques differs fundamentally from chromatographic
methods. In electrophoresis, ionic analytes migrate with a constant velocity $v$ that can be expressed as the product of the applied electric potential $E$ and the electrophoretic mobility $\mu$ (Equation 1):

$$v = \mu E$$

with the mobility being dependent on the charge density (charge/mass ratio) of an ionic species. For spherical molecules $\mu$ can be expressed (Equation 2) as:

$$\mu = \frac{q}{6\pi r\eta}$$

where $q$ is the charge of the analyte, $r$ is the Stokes radius of the hydrated species and $\eta$ is the viscosity of the separation medium. For peptides and proteins, which may not always be spherical, interpretation of the electrophoretic mobility in terms of molecular size and charge is more complex. However, as can be deduced from the theory and empirical data available, the electrophoretic mobility of a peptide or protein is proportional to the actual charge and inversely proportional to the size. The charge of weak electrolytes depends on the pH of the separation buffer according to the acid–base equilibrium of the electrolyte. The degree of ionization of weak acids and bases and, thus, the effective electrophoretic mobility, is therefore a function of the buffer pH and the dissociation constant ($pK_a$) of the compounds. Moreover, in CE the velocity of an analyte will also depend upon the magnitude of the unselective electroosmotic flow (EOF) generated by the pH-dependent ionization of the silanol groups of the fused-silica capillary wall, resulting in a flow of the bulk solution towards the cathode.

Among the different CE techniques, free solution capillary zone electrophoresis (CZE) and micellar electrokinetic chromatography (MEKC) have been applied to the separation of peptide diastereomers. In MEKC, surfactants above their critical micelle concentration are applied as pseudostationary phases. A separation in MEKC is the result of differences in the partitioning of solutes between the micelles and the aqueous buffer; MEKC is typically applied to the separation of hydrophobic compounds. Whereas in CZE a separation is based on

the mobility difference between analytes, MEKC is governed by a chromatographic separation principle and an electrophoretic migration principle. For a comprehensive treatment of the theory and the various CE separation techniques the reader is referred to the numerous monographs on this topic as well as to the relevant articles of this encyclopedia – Capillary Electrophoresis and Micellar Electrokinetic Chromatography.

With a few exceptions where resolutions of diastereomeric peptides were performed using chiral additives, the published separations were primarily achieved in achiral environments. It is usually possible to separate diastereomers using chiral additives as well, but this is outside the scope of the current article. The use of chiral selectors also allows the simultaneous separation of enantiomers and diastereomers of small peptides, which has been mentioned in several recent reviews. A comprehensive treatment of chiral CE has been published by Chankvetadze.

3.1 Capillary Zone Electrophoresis

Diastereomeric peptides have been preferentially separated by CZE at acidic buffer pH (Table 8), i.e. at pH values in the region of the pKₐ values of the carboxyl groups of the C-terminus or in side chains of Asp or Glu. Small differences in the pKₐ values of the carboxylic acid groups of the diastereomers result in different effective mobilities of the peptides. However, it is also possible to resolve diastereomers at basic pH values in the region of the pKₐ of the amino groups, as demonstrated for Asp and Glu di- and tripeptides. One reason for the preference of acidic buffers is the fact that the unspecific EOF is negligible at low pH. The large EOF at higher pH values (>4) might interfere with the separation. The EOF can be suppressed by dynamic or permanent coating of the inner capillary wall, but this approach has not been exploited for the resolution of peptide diastereomers at present. Peptides containing up to 36 amino acids have been separated by CZE. Moreover, the first resolution of peptide diastereomers by nonaqueous CZE has been reported.

Chiral selectors such as cyclodextrins have been added in a few cases. The observed separations are due to the formation of transient diastereomeric complexes between the selectors and the peptide analytes. This results in different effective charge densities caused by different spatial orientations of the diastereomers, or by specific interactions between the selectors and the host molecules.

In contrast to the chromatographic separation techniques no rule concerning the migration sequence of the diastereomers of di- and tripeptides can be deducted from the published data (Table 8). It is interesting to note that replacement of Asp by Glu, i.e. insertion of a methylene moiety, led to opposite migration behavior. Although the LL diastereomer of the α isomers of Asp-PheOMe and Asp-PheNH₂ migrated faster than the respective LD epimers, the LD diastereomers of α-GluPheOMe and α-GluPheNH₂ migrated faster than the LL epimers.

3.2 Micellar Electrokinetic Chromatography

As peptides are usually polar compounds, most analyses including stereoisomer separations have been performed in the CZE mode. However, the resolution of the diastereomers of several hydrophobic peptides and N-derivatized peptides have been reported using neutral as well as ionic detergents as pseudostationary phase.

Anionic surfactants are typically used in MEKC, with the analyte distribution between the phases governed mainly by hydrophobic interactions with the sodium dodecylsulfate (SDS) alkyl side chains. Small peptides interact only to a limited extent with the micelles, often resulting in a separation. Larger peptides and proteins can interact much more strongly so that a separation is not achieved. Water-soluble organic solvents such as acetonitrile and methanol have been successfully employed to decrease these interactions by reducing the polar nature of the separation buffer. An alternative approach is the use of polar nonionic surfactants such as Brij® 35 or Tween® 20 as micelle-forming agents having weaker interactions with peptides. Although ionic detergents such as SDS or sodium cholate possess an electrophoretic self-mobility, neutral detergents such as Tween® 20, Tween® 40 and Brij® 35 migrate only with the EOF.

Typically, high-pH buffers are used in MEKC separations of peptides (Table 9). At these pH values the peptides are negatively charged and possess a self-mobility towards the anode as do the negatively charged surfactants such as SDS. Thus, high pH values are required to generate a sufficiently high EOF so that the peptides can still be detected at the cathodic end of the capillary. When neutral surfactants are employed peptides can also be separated at low pH when they are positively charged and migrate towards the cathode. Compared to the system using SDS and high-pH buffers, this results in a reversal of the diastereomer migration order. It is interesting to note that a reversal of the migration order was also observed for the peptide drug lisinopril by switching the surfactant from sodium cholate to SDS. This may be attributed to the chiral recognition ability of the chiral surfactant cholated towards the lisinopril diastereomers as compared to the achiral SDS. The use of a cationic detergent

3.3 Method Development

The electrophoretic mobility of peptides is proportional to the charge and inversely proportional to the size. As peptides are weak electrolytes their degree of ionization and, thus, the effective electrophoretic mobility are therefore a function of the buffer pH and the pK<sub>a</sub> of ionizable groups. The factor that most effects electrophoretic mobility is charge, hence pH is the most significant variable for peptide CE separations.

Most diastereomer separations in the CZE mode have been carried out between pH 2 and pH 4, i.e. in the range of the pK<sub>a</sub> values of carboxyl groups located either at the C terminus or in the side chain of Asp or Glu. Method development for CE peptide diastereomer separations starts by selecting the appropriate pH, the most important parameter for optimizing the selectivity. Phosphate buffers have been primarily used, but acetate or other buffers can be applied to match ion mobility. The second step is the optimization of the type of buffer ion, the ionic strength of the buffer, the separation voltage, and the length of the capillary. Further optimization may include the use of buffer additives such as organic solvents, metal ions, ion-pair reagents, surfactants, chiral selectors, etc. in order to maximize differences between the diastereomers or to mask interactions between the peptides and the capillary wall. As CE is a relatively young technique not all factors influencing a separation are fully understood. Thus, trial-and-error still governs method development in CE, including the separation of peptide diastereomers.

PEPTIDE DIASTEREOMERS, SEPARATION OF

Specific oxidative modifications of amino acids in proteins are used to monitor the exposure of biological tissue to oxidative stress. This article introduces the most prevalent oxidative amino acid modifications which have been characterized in vivo and summarizes the analytical methodology for their identification and quantification.

1 INTRODUCTION

The oxidative posttranslational modification of proteins is an important feature of biological oxidative stress, aging, and the manufacturing and storage of protein pharmaceuticals. Often, but not always, protein oxidation is accompanied by structural and functional changes, loss of thermal stability, and accelerated turnover. However, to what degree these parameters are affected by oxidation depends on the nature and the extent of modification. Much effort has been spent on the analysis of certain amino acid and protein oxidation products as general ‘biomarkers’ of oxidative stress, e.g. protein carbonyls, and indicators of the action of certain reactive oxygen and nitrogen species, e.g. 3-nitrotyrosine (3-NY) and o- and m-hydroxyphenylalanine.

Such strategies are valuable to demonstrate the exposure of tissue to oxidative processes. However, attempts to deduce the severity of oxidative stress from a quantitative measurement of protein oxidation products need to be discussed carefully with regard to the following issues. Based on sequence, structure and location in tissue, different proteins may show (i) different sensitivities towards oxidation in general, and (ii) different product patterns for a single oxidant. For example, by measurement of protein carbonyl formation, Shacter et al. identified fibrinogen as particularly sensitive to oxidative stress in vivo. In contrast, the age-dependent in vivo oxidation of calmodulin showed no significant accumulation of protein carbonyls but high levels of methionine (Met) sulfoxide instead. It is also important to evaluate the experimental method relative to the question to be answered. For example, Leeuwenburgh et al. quantified 3-NY in skeletal muscle homogenates of rats and concluded that biological aging is not accompanied by an increase in 3-NY formation. However, when specific skeletal muscle proteins were analyzed, a significant accumulation of 3-NY (up to 3.5 mol/mol) on the SERCA2a isoform of the sarcoplasmic reticulum Ca-ATPase was observed, associated with a loss of function. In essence, functionally important oxidative modifications of proteins can be missed by the analysis of whole tissue homogenate when the proteins are expressed in low yields. In the following, we shall briefly review some general analytical strategies, followed by methods developed for the most prevalent oxidative modifications, especially in view of low sample volumes derived from tissue or cell cultures.

2 GENERAL STRATEGIES

If sample volume permits, several standard techniques are available for the characterization of oxidative protein...
modifications. Proteins may be isolated or separated by gel electrophoresis. Both the isolated protein or specific bands on a gel may be subjected to microsequencing techniques, proteolytic digestion, high-performance liquid chromatography (HPLC) or capillary electrophoresis, and mass spectrometric analysis. These techniques have been described in detail elsewhere in this volume.

3 SPECIFIC STRATEGIES FOR SELECTED MODIFICATIONS

3.1 Protein Carbonyls

There are various routes to protein carbonyls involving either the direct oxidation of an amino acid side chain (predominantly lysine (Lys), arginine (Arg), proline (Pro), threonine (Thr)) or the covalent attachment of lipid peroxidation products (e.g. 4-hydroxy-2,4-unsaturated aldehydes via Michael addition) to a protein (protein-associated carbonyls).

Hence, the measurement of protein carbonyls does not necessarily indicate protein oxidation only but, more generally, the occurrence of oxidative processes in the environment of a protein. Because of its sensitivity, it has evolved into a routine tool to assay oxidative stress. Usually, proteins are derivatized with 2,4-dinitrophenylhydrazine (2,4-DNPH) to yield the corresponding hydrazones. The latter can be directly quantified by ultraviolet (UV) spectroscopy ($\lambda = 360–370$ nm). However, specific care must be taken with regard to loss of protein during washing steps and the potential contamination by excess 2,4-DNPH or nucleotides. Such problems may be circumvented using size-exclusion chromatography and dual wavelength detection at 280 and 370 nm. Initially, proteins can be concentrated by precipitation with trichloroacetic acid or ammonium sulfate, and resolubilized for derivatization with either 6.0 M guanidine hydrochloride or sodium dodecyl sulfate (SDS). However, in their work on soluble proteins from rat brain, Floor and Wetzel noted that about half of the proteins were not redissolved unless 6.0 M guanidine was supplemented with 50% formic acid. Initially, a Zorbax GF450 column was recommended for the chromatographic step, mostly based on its performance tolerating higher flow-rates and back pressure associated with the use of a guanidine/phosphate buffer as the eluent. However, these problems may be avoided, and other columns used, when the size exclusion chromatography is performed in SDS. Once derivatized with 2,4-DNPH, proteins can also be separated by gel electrophoresis and detected by Western blotting or enzyme-linked immunosorbent assay (ELISA) using an antibody against the 2,4-dinitrophenyl moiety. Alternative labeling reagents for protein carbonyls include digoxigenin-hydrazide (followed by staining with an anti-digoxigenin antibody) and biotin-4-amidobenzoic hydrazide, visualized by streptavidin conjugated to a fluorescent dye, dichlorotriazinylaminofluorescein. Protein carbonyls can also be reduced to the corresponding alcohols with NaBH₄ and proteins or amino acid hydrolysates monitored by scintillation counting.

A specific pathway to the formation of protein-associated carbonyls involves the addition of the lipid peroxidation product 4-hydroxynonenal (4-HNE) to proteins. Antibodies against protein-bound 4-HNE have been used for the screening of 4-HNE-protein adducts formed during conditions of oxidative stress, e.g. for oxidized low density lipoprotein (LDL) where 4-HNE-adducts were formed with Lys and histidine (His). Subsequently, 4-HNE-addition to various His residues of apoB was confirmed by mass spectrometry (MS).

3.2 Cysteine

The sulfhydryl group of cysteine is easily modified by various reactive oxygen and nitrogen species. Products include sulfenic, sulfinic or sulfonic acid, disulfide, nitrosocysteine and nitrocysteine. As the oxidation state of cysteine often determines the structure, function and properties of a protein, it is important to assess the cysteine content of proteins under investigation. The most common method for determining protein cysteinyl residues is derivatization with Ellman’s reagent (5,5′-dithiobis (2-nitrobenzoate) DTNB). This assay, although rapid and reproducible, has the disadvantage of lack of sensitivity at cysteine concentrations below 3 $\mu$M. More sensitive assays have been developed based on fluorescent reagents such as rhodamine, dansyl chloride, fluoresceine isothiocyanate derivatives, monobromobimane, and maleimide derivatives. After modification, the protein can be digested and the labeled fragments can be quantified by fluorescence spectroscopy and/or reversed phase high-performance liquid chromatography (RP-HPLC) coupled to a fluorescence detector. For the detection of protein disulfides, cysteine residues are alkylated (i.e. with iodoacetate) before the protein is reduced and the resulting additional cysteine residues labeled with the fluorescent tag. When a fluorescence detector is not available, cysteine residues can be labeled with derivatizing agents containing UV chromophores. The use of hydrophobic chromophores for the selective isolation of cysteine-containing peptides was first reported by Chang et al. Recently, the identification of the functionally important cysteine residues in Ca-ATPase through
derivation with 4-dimethylaminophenyl-azophenyl-4'-maleimide (DABMI) was reported by Viner et al.\(^{32}\) After modification, the protein was digested and the resulting peptides were analyzed by HPLC coupled with MS. The excess label needs to be removed with washing with organic solvents (dimethylformamide (DMF)).\(^{33}\)

Papain amplification was reported as a sensitive assay for the determination of cysteine in proteins.\(^{29}\) The basis of this assay is to generate a stoichiometric amount of active enzyme rather than a level of a protein-bound chromophore or fluorophore. Once the active enzyme is generated, it produces a chromophoric product proportional to the amount of active enzyme. Since this is an amplification assay the sensitivity and detection limits are proportional to the incubation time of the reactivated papain with substrate. Wright et al. reported a 10-fold increase in sensitivity over an improved Ellman’s assay.\(^{29}\)

Other chemical modifications have been used in conjunction with chromatographic methods. Ming et al. successfully quantified the eight cysteines of brazzein, a natural high potency protein from a wild West African plant. The protein’s cysteine residues were modified by 4-vinylpyridine and then desalted by RPHPLC. The eluted samples were analyzed by electrospray ionization/mass spectrometry (ESI/MS).\(^{34}\) Another chemical modification to quantitate cysteines employees a selective cleavage followed by analysis with matrix-assisted laser desorption ionization/time-of-flight/mass spectrometry (MALDI/TOF/MS).\(^{35}\) The modification involves the specific reaction between free sulfhydryls with 2-nitro-5-thiocyanobenzoic acid (NCTB). The N-terminal peptide bond is cleaved under alkaline conditions to form an amino-terminal peptide and a series of 2-iminothiazolidine-4-carboxyl peptides can be mapped to a sequence by MALDI/TOF/MS. This assay can be performed with native and reduced protein in order to differentiate between free and disulfide-linked cysteine residues.

Weiner\(^{36}\) described a method to quantitate protein cysteine residues by spin labeling, employing a symmetrical disulfide-linked biradical, bis(2,2,5,5-tetramethyl-3-imidazoline-1-oxyl-4-yl)-disulfide. The reaction of protein cysteine residues with the biradical cleaves the disulfide bridge and generates monoradicals which can be monitored by electron paramagnetic resonance (EPR). The reaction rate is proportional to the reactivity, i.e. accessibility of the cysteine residue. This sensitive method allows the quantitation of \(<10^{-12}\) M, and provides a useful tool to study protein folding.

With the discovery of nitric oxide (NO) as an important biological messenger, the detection of cysteine \(S\)-nitrosylation has become an important area of research. The location of \(S\)-nitrosocysteine residues in proteins can be achieved by MS; however, during the preparation of the protein reducing agents need to be avoided. There is also always the problem that trans-nitrosation reactions may occur in proteins which contain several free cysteine residues. Fluorometric and colorimetric techniques for the detection of \(S\)-nitroso compounds utilize the metal-catalyzed liberation of NO which combines with an appropriate precursor(s), i.e. 2,3-diaminonaphthalene to yield a fluorescent 2,3-naphthotriazole (NAT), or sulfuramidate and \(N\)-(1-naphyl)ethylenediamine dihydrochloride to yield a chromophore.\(^{37,38}\)

Thomas and colleagues developed an isoelectrofocusing method for the separation of \(S\)-nitrosylated protein from other isoforms such as native, oxidized and \(S\)-glutathiolated protein.\(^{39}\) This method has been applied to detect protein heterogeneity in cell lysates. However, in order to utilize this method for the identification of specific protein modification products, the method shall be standardized carefully in vitro.

### 3.3 3-Nitrotyrosine

Since it has been recognized that 3-NY is a product of the reaction of peroxynitrite (ONOO\(^{-}\)) with tyrosine (Tyr) residues,\(^{17}\) and that 3-NY is present in human atherosclerotic tissue,\(^{40}\) there has been much interest to analyze the presence of 3-NY in tissue as a ‘biomarker’ for the formation and reaction of peroxynitrite. It is now clear, however, that, besides peroxynitrite, several reactive nitrogen species and enzymatic systems, utilizing nitrite, can generate 3-NY so that the presence of 3-NY in tissue is indicative collectively for the formation of reactive nitrogen species.\(^{41}\)

Both free and protein-bound 3-NY can be detected by various analytical techniques and it is recommended to use at least two independent methods to monitor 3-NY. Potential artefacts based on a single technique have been reported recently. When Kaur et al. analyzed human brain tissue from patients with various neurodegenerative diseases (Parkinson’s disease, Huntington chorea, Alzheimer’s disease, etc.) for 3-NY they detected by HPLC analysis a peak with a retention time matching that of authentic 3-NY.\(^{42}\) However, further analysis by diode array UV spectroscopy and MS revealed that the monitored peak was not 3-NY. The presence of this artefact was confirmed by Althaus et al.\(^{43}\)

Various techniques have been developed for the analysis of both free and protein-bound 3-NY in/from tissue. Tissue homogenate can be screened by Western-blotting using a monoclonal anti-3-NY antibody.\(^{44,45}\) Two important control experiments involve the incubation of the antibody with 3-NY (antigen-competed antibody) and the chemical reduction of 3-NY to 3-aminotyrosine (3-AY) with dithionite (removal of antigen) prior to Western blotting. With the same antibody, 3-NY-containing
proteins can be immunoprecipitated for further characterization by sequencing, peptide mapping, amino acid analysis and/or MS.\(^{(46)}\) Immunoprecipitation is, of course, also possible with antibodies specific to the protein of interest. However, it was noted that nitrated proteins are sometimes less well recognized by protein-specific antibodies as are the native non-modified proteins.\(^{(47)}\) When protein-bound 3-NY is to be analyzed as free 3-NY after hydrolysis of the protein, special attention has to be paid to the hydrolysis procedure. It has been shown that 3-NY can be formed during acid hydrolysis when contaminating nitrite is present in the reaction mixture.\(^{(48)}\) Contaminating nitrite can be removed by exhaustive dialysis. Alternatively, the protein may be proteolyzed enzymatically, for example by pronase E. However, enzymatic digestion always raises the possibility of incomplete cleavage or contamination of the protein sample through autodigestion of the proteolytic enzyme.

For the most part, the analysis of free 3-NY involves HPLC coupled to UV or electrochemical detection (after reduction to 3-AY, fluorescence detection may be used as well; however, 3-AY is unstable and slowly reoxidizes). 3-NY has been analyzed in its free or N-derivatized form (N-acetylation, derivatization with phenyl isothiocyanate; PITC) and, electrochemically, after reduction to 3-AY.\(^{(4,14,45,48–50)}\) Electrochemical detection has been combined with post-column UV photolysis in a TiO\(_2\)-coated reaction coil.\(^{(51,52)}\) An alternative strategy for a more specific detection of 3-NY (and other Tyr oxidation products) involves isotope dilution MS. After reaction with \(n\)-propanol (C-terminus) and heptafluorobutyric acid anhydride (N-terminus and phenoxy group) the resulting 3-NY derivative is analyzed by gas chromatography (GC)/negative-ion electron capture MS.\(^{(53)}\)

### 3.4 Other Modifications of Tyrosine

Several other characteristic products of Tyr modification \((2–8)\) have been identified in vitro and in vivo for several pathologic conditions associated with oxidative stress (atherosclerosis, nuclear cataractogenesis, aging etc.).\(^{(12,53–55)}\)

Some of these products are characteristic for specific modifying agents and intermediates such as 3,4-dihydroxyphenylanaline (DOPA) \((2)\) (hydroxyl radicals),\(^{(54,55)}\) 3-chlorotyrosine (HOCI, Cl\(_2\)) \((3)\) \((49,53,56)\) 3-bromotyrosine (HOBr) \((4)\) \((57)\) \(o,\dot{\text{o}-dityrosine (5)\), isodityrosine \((6)\), trityrosine \((7)\), and pulcherosine \((8)\) (tyrosyl radicals).\(^{(58)}\) GC/MS analysis has been useful especially for the analysis of 3-chloro- and 3-bromotyrosine as well as \(o,\dot{\text{o}-dityrosine. Alternatively, these products can be detected by HPLC coupled to UV (direct detection or derivatization with orthophthalaldehyde; OPA), fluorescence (dityrosine, trityrosine, pulcherosine; 3-chlorotyrosine after derivatization with 1-nitroso-2-naphtol) or electrochemical detection (3-chlorotyrosine). Especially, \(o\)- and \(m\)-hydroxyphenylalanine have been used as indices for the formation and reaction of hydroxyl radicals.\(^{(8,12)}\) These products can be monitored by several amino acid analysis techniques as well as GC/MS.

#### 3.5 Oxidative Modifications of Tryptophan

The oxidation of tryptophan (Trp) leads to various aromatic hydroxylation products as well as fluorescent products such as \(N\)-formylkynurenine.\(^{(59)}\) The latter exhibits an emission maximum around \(\lambda_{\text{em}} = 430\) nm and peptides containing \(N\)-formylkynurenine are conveniently detected by HPLC coupled to fluorescence detection. We note that a common Tyr oxidation product, \(o,\dot{\text{o}-dityrosine shows an emission maximum around \(\lambda_{\text{em}} = 420\) nm. Hence, when fluorescent oxidation products are present in proteins their identity shall be confirmed by amino acid analysis and/or MS.

#### 3.6 2-Oxo-histidine

Based on their metal-binding properties, protein His residues are preferred sites for site-specific metal-catalyzed oxidation. General principles underlying the site-specific metal-catalyzed oxidation of proteins have been established with the protein glutamine synthetase\(^{(60,61)}\) which was also shown to be a target...
for oxidation during oxidative stress. The specific sensitivity of His to metal-catalyzed oxidation is probably best documented in glutamine synthetase where His<sup>269</sup>, located in the sequence Met/His<sup>269</sup>-Cys-His/Met, is oxidized whereas the generally more oxidation-sensitive residues Cys and Met are left intact. Subsequently, the metal-catalyzed modification of His residues was demonstrated for several other peptides and proteins (for a recent review, see Schöneich<sup>63</sup>).

One characteristic oxidation product of His is 2-oxo-His<sup>9</sup> though, depending on the extent of His oxidation, higher oxidation products of His may be observed.

2-Oxo-His can be conveniently detected by classical amino acid analysis methods including ion-exchange chromatography and postcolumn derivatization or reversed-phase chromatography coupled to precolumn derivatization with OPA or 6-aminoquinoyl-N-hydroxysuccinimidyl carbamate (AQC)<sup>64,65</sup>. Importantly, 2-oxo-His is relatively unstable during acid hydrolysis (6 M HCl) unless dithiothreitol (>20 mM) is included in the reaction mixture. Especially for the derivatization with OPA, the pH of the reaction mixture needs to be lowered towards pH 8.0 as 2-oxo-His is chemically too unstable at higher pH values. Alternatively to the fluorescence detection of derivatized 2-oxo-His, 2-oxo-His may be selectively monitored directly by HPLC coupled to an electrochemical detector (ECD) set at 0.85 V.<sup>66</sup>

### 3.7 Hydroxylation of Valine, Leucine, and Lysine

Especially when exposed to the highly oxidizing hydroxyl radical, proteins can accumulate oxidative modifications also on otherwise less reactive aliphatic amino acid side chains such as those of leucine and valine.<sup>67,68</sup> Initially, the reaction of hydroxyl radicals with these amino acids generates hydroperoxides of which several isomers and diastereomers have been characterized in detail for both valine and leucine. The latter can be reduced to the corresponding hydroxy derivatives by NaBH<sub>4</sub> or other, biologically relevant reductants, and analyzed by reversed-phase chromatography using pre- or postcolumn derivatization with OPA. Some structures of hydroxyvaline<sup>68</sup> are shown (10–12):

It was proposed that the hydroxylation of valine and leucine serves as a biomarker specifically for the exposure of proteins to hydroxyl radical-generating systems. In vivo, hydroxyvaline and hydroxyleucine have been characterized for various diseased tissue such as advanced human atherosclerotic plaques<sup>55</sup> and nuclear cataractogenesis.<sup>54</sup> The oxidation of valine and leucine was also observed during the incubation of collagen with glucose, i.e. as a result of glycation-dependent oxidation processes.<sup>69</sup>

Lys is quite sensitive to metal-catalyzed oxidation which usually results in N-dealkylation and the formation of protein carbonyls (see above). However, when exposed to free hydroxyl radicals other characteristic oxidation products have been detected such as 3-, 4- and 5-hydroxylysine (in vitro the hydroxylation is preceded by hydroperoxide formation and the hydroperoxides reduced with NaBH<sub>4</sub>; in vivo, alternative biological reductants may operate).<sup>70</sup> Whereas 5-hydroxylysine is also generated enzymatically by lysyl oxidase, 3- and 4-hydroxylysine have been proposed as indices for (hydroxyl) radical-mediated protein oxidation. These products have been monitored by HPLC analysis following derivatization to their 9-fluorenylmethylchloroformate (FMOC)-derivatives.

### 3.8 Methionine Sulfoxide

L-Methionine sulfoxide (L-MetSO) is a common oxidation product of L-Met in vivo and in vitro which can be conveniently detected by classical amino acid analysis methods. Proteins can be hydrolyzed with 1 M NaOH or 4 M methanesulfonic acid (CH<sub>3</sub>SO<sub>3</sub>H) whereas hydrolysis with 6 M HCl is not recommended as under such conditions MetSO can convert back to Met.

An important detail of L-Met oxidation is the potential formation of two MetSO diastereomers, L-Met-<i>d</i>-SO (13) and L-Met-<i>L</i>-SO (14). The occurrence of diastereoselective oxidation can indicate the diastereoselective chemistry of an oxidant or a specific conformational arrangement of the target L-Met residue in a protein. In vivo, other parameters may contribute to the accumulation of specific L-MetSO diastereomers such as the diastereoselective repair of L-MetSO by the
enzyme Met sulfoxide reductase or a selective turnover of oxidized protein. L-Met-d-SO and L-Met-l-SO can be separated by reversed phase chromatography after precolumn derivatization with 4-dimethylamino-azobenzene-4'-sulfonylchloride (DABSYL)\(^{(71)}\) or OPA.\(^{(72)}\) In order to avoid reduction or racemization of the L-MetSO diastereomers during recovery from an oxidized protein, the protein was subjected to proteolytic cleavage, and isolated proteolytic fragments to further digestion by carboxypeptidase Y.\(^{(71)}\) Both L-MetSO diastereomers were separated well from other amino acids in these digests by reversed-phase chromatography after precolumn derivatization with OPA.

The location of Met residues in proteins has been routinely assessed through cyanogen bromide (CNBr) cleavage followed by N-terminal sequencing of the resulting fragments. By comparison of the fragments from a native and oxidized protein, the location of MetSO residues can be characterized. Recently, Levine et al. have optimized a simultaneous sequencing procedure on a Hewlett Packard G1005A automated sequencer in order to detect the locations of MetSO in oxidized glutamine synthetase.\(^{(73)}\) Glutamine synthetase was cleaved with CNBr, the resulting fragments loaded onto the sequencer column, and the pattern of phenylthiohydantoin (PTH)-amino acids recorded. The subtle but evident changes in these patterns caused by oxidation of the protein were sufficient to identify the locations of the MetSO residues.

### 3.9 Advanced Glycation Endproducts

Protein glycation results in a large manifold of structures of which only a fraction has been chemically characterized in detail. One prominent glycation endproduct is carboxymethyllysine (CML) which can be conveniently monitored by GC/MS as trifluoroacetyl methyl ester derivative.\(^{(74)}\) Furthermore antibodies against CML have been developed and used, for example, to detect CML in atherosclerotic lesions of human aorta.\(^{(75)}\) The mechanisms of CML formation have been studied in quite detail and it is interesting to note that CML formation occurred faster as a result of lipid peroxidation as compared to glucose oxidation.\(^{(74)}\)

CML formation is not specifically indicative of glucose oxidation.

### 4 CONCLUSIONS

This brief article illustrates the variety of possible products resulting from the posttranslational oxidation of proteins. It can be anticipated that an increasing amount of products will be characterized in the future as our understanding of free radical reactions with proteins develops. It is now mandatory not only to study which of these products are characteristic for various pathological conditions but also to identify the affected proteins and potential functional consequences. The latter may directly correlate with physiological dysfunctions.

### ACKNOWLEDGMENTS

Much of our research on the oxidative modifications of peptides and proteins was supported by the NIH (PO1AG12993 and GM08359).

With the rapid advances in recombinant DNA technologies, it became possible to express large amounts of virtually any protein in different host cells, including bacteria, yeast, insect, and mammalian cells. Efficient purification methods are becoming more and more important as the need for protein drugs continues to expand. In this article we cover some basic procedures for the purification of soluble recombinant proteins expressed in Escherichia coli and methods to obtain soluble and active protein from insoluble and inactive inclusion bodies. Finally, methods for the purification of native intrinsic membrane proteins from human lymphoblastoid cell lines, using immobilized monoclonal antibodies (mAbs), are presented.

As a first step, the protein of interest has to be released into an aqueous extract. Following extraction, residual debris and intact cells are removed by centrifugation. Nucleic acids are either hydrolyzed or precipitated to reduce the viscosity of the extract. A crude enrichment for the protein of interest is made based on its differential solubility in ammonium sulfate. This is then followed by high-resolution chromatographic methods. The type of chromatographic matrices and the order of their use are evaluated in pilot experiments for column selection. By combining the specificity and discriminatory powers of various chromatographic techniques, it is possible to isolate rapidly a single protein species from a heterogeneous mixture.

For the purification of native intrinsic membrane proteins, the use of immunoaffinity methods is emphasized, since specific mAbs may be obtained even against low-copy-number membrane proteins by reducing a multispecific antibody response to a series of monospecific responses by cloning. The use of immobilized, highly specific mAbs is demonstrated in the purification of human leukocyte antigen D-related (HLA-DR) antigens.

Rapid advances in complete genome sequences provide us with a continuously expanding number of new potential therapeutic targets. These proteins will have to be purified and characterized. The existence of a functional protein blueprint will be invaluable not only for the diagnosis but possibly also for the treatment of many diseases.

1 INTRODUCTION

The term “protein” comes from the Greek proteios, meaning “of first importance”, and its use is attributed to Berzelius around 1838. Proteins were isolated from various plant and animal tissues already in the early part of the 19th century. Fractionation methods for proteins using alcohols, acetone and various salt solutions were developed and formed the basis of protein purifications for the next 100 years. Until relatively recently, most protein purification took place in university laboratories in order to obtain samples for enzymatic and structural studies. With the advances in recombinant DNA technology, it became possible to express large amounts of virtually any protein in different host cells, including bacteria, yeast, insect, and mammalian cells. Cloning genes, encoding human proteins, such as interferon, growth hormone and insulin, into bacteria has allowed their production in amounts required for their widespread therapeutic use. Efficient purification methods become more and more important as the need for these protein drugs continues to expand. A high level of expression, of course, facilitates protein purification, where we have to remove contaminants from a highly enriched product rather than try to purify a small component from a complex mixture. Nevertheless, separating the desired recombinant protein from a background of endogenous bacterial contaminants remains an essential and often difficult task.
2 PURIFICATION OF RECOMBINANT PROTEINS, EXPRESSED IN ESCHERICHIA COLI

2.1 Purification of Soluble Proteins

2.1.1 Extracting the Protein

As a first step in recombinant protein purification, we have to disrupt the bacterial host in order to release the protein of interest into an aqueous “extract”. Bacterial cells are typically lysed by using any of the mechanical or chemical methods listed in Table 1.

Repeated cycles of freezing and thawing apparently liberate recombinant proteins from the bacterial cytoplasm, presumably through transient pores, without releasing the bulk of endogenous host proteins. Bacterial pellets, expressing a recombinant protein, are frozen in a dry-ice–ethanol bath and thawed in an ice–water bath. The cycle is repeated three times before the addition of a standard buffer for extraction.

Grinding in alumina is a good way to open cells for the extraction of labile proteins. One part by weight of cell paste is mixed with 2.5 parts by weight of alumina and ground in a precooled mortar until a smooth consistency is obtained. Buffer (2 parts by weight) and deoxyribonuclease (DNase) (10 µg mL⁻¹) are added before the alumina and cell debris are removed by centrifugation at 5000 g for 15 min.

Larger amounts (100–1000 g wet weight of cell paste) can be opened by grinding with glass beads in a water-jacketed Waring® blender. Frozen bacterial paste is mixed with 1 part by weight of buffer and 2.5 parts by weight of glass beads (Superbrite® 100 beads from Minnesota Mining and Manufacturing Co.) in a cooled Waring® blender and treated for 10–15 min at high speed. To reduce viscosity, DNase is added to 10 µg mL⁻¹ of cell suspension.

Small amounts of cells, up to 1 g (about 10¹² E. coli), can be easily opened by sonication, although spherical bacteria such as Staphylococcus sp. are relatively resistant to this method. Cell suspension, up to 2 × 10¹¹ cells mL⁻¹, is treated on ice for 3–4 min with bursts of 30 s of sonication at about 50 W.

A combination of lysozyme (0.2 mg mL⁻¹)–ethylene-diaminetetraacetic acid (EDTA) (2 mM) treatment followed by osmotic lysis is often successful on a small to medium scale. Gram-positive species are most susceptible to lysozyme, although the inclusion of a nonionic detergent (0.1%) in combination with lysozyme–EDTA works well for Gram-negative species also. Enzymatic procedures may be expensive on a large scale; moreover, the enzyme added is one more contaminant that must be subsequently removed later.

Some common chemical release methods include strong denaturing agents such as urea, guanidine hydrochloride and detergents such as sodium lauryl sarcosinate and sodium lauryl sulfate. These methods, although effective in opening recombinant E. coli cells, should be reserved for cases where the recombinant protein is present in insoluble inclusion bodies. Perhaps the most popular methods to open bacteria on a medium to large scale include French® pressure cell treatment, Manton–Gaulin® homogenization and Dyno-Mill® cell disruption. treatment, 25 g (wet weight) of *E. coli* paste, expressing a recombinant protein, is suspended in 50 mL of breaking buffer (BB): 100 mM N-(2-hydroxyethyl)piperazine-N'-(2-ethanesulfonic acid) (HEPES)–NaOH, pH 8.0, containing 10% glycerol, 1 mM MgSO₄ and 150 mM NaCl. Benzonase® (Merck) is usually added to 250 units mL⁻¹ to hydrolyze DNA and RNA present. The protease inhibitors Trasylol® (Bayer) and ε-aminoacaproic acid (Serva) are added to 100 units mL⁻¹ and 5 mM, respectively. A nonionic detergent, either Triton X-100®, Nonidet P-40 (NP-40) or Brij-58, is added to 0.1% final concentration and the cells are broken in a precooled French® pressure cell (SLM Instruments) at 20,000 lb in⁻². One or two passages are usually sufficient to obtain complete cell breakage. Some proteins, such as peptide deformylase, are extremely sensitive to oxidation. This protein is an amide hydrolase and utilizes a ferrous ion as the catalytic metal.(7) Atmospheric oxygen can rapidly oxidize the catalytic Fe²⁺ ion of deformylase into a catalytically inactive Fe³⁺ form. The inclusion of scavengers of O₂, such as the glucose oxidase and catalase system, was found to be effective in preserving deformylase activity. We found that for some recombinant proteins the inclusion of catalase and superoxide dismutase (SOD) at 10 and 0.1 µg mL⁻¹, respectively, in most of the buffers during purification has helped to preserve enzymatic activity.

The pH of the BB is dictated by the isoelectric point (pI) of the protein to be purified, and should be at least 1 pH unit higher, to prevent isoelectric precipitation. Proteins are least soluble at their pI and once precipitated they might need denaturing conditions for resolubilization. We use a BB with high buffering capacity (100 mM) since we found that biomasses, especially fermenter grown, have a pH around 5. Glycerol is included because it minimizes hydrophobic interactions with various surfaces, stabilizes proteins(8) and at higher concentration (30–50%) can also act as a cryoprotectant.

For the purification of DNA binding recombinant proteins (DNA gyrase, helicases, topoisomerases, etc.), the use of nucleases should be avoided since residual nuclease in the purified protein preparation would hydrolyze the DNA used in the DNA shift experiments. In these cases the BB should contain higher salt concentration (300 mM NaCl) to reduce ionic interactions between the negatively charged DNA backbone and positively charged domains on protein molecules. To reduce viscosity, after cell breakage DNA can be precipitated by polyethyleneimine (PEI) (Polyvin P®), protamine sulfate or streptomyacin sulfate.(9)

Proteolytic digestion, especially during the early stages of purification, might be a problem. Many investigators therefore include a whole cocktail of protease inhibitors in the extraction buffer.(10) We routinely use Trasylol® and ε-aminoacaproic acid. Trasylol®, also known as aprotinin or kallikrein inhibitor, is a broad-spectrum protease inhibitor that inhibits trypsin, chymotrypsin, trypsinogen, urokinase, kallikrein, elastase, plasmin, and tissue and lysosomal proteinases. ε-Aminoacaproic acid inhibits chymotrypsin, fibrinolysin and plasmin. The use of protease inhibitors that covalently react with proteins, such as phenylmethylsulfonyl fluoride (PMSF), diisopropyl fluorophosphate (DFP), N-α-p-tosyl-L-lysine chloromethyl ketone (TLCK) and N-tosyl-L-phenylalanine chloromethyl ketone (TPCK) is avoided. These inhibitors can modify amino acid side chains on proteins(11) and, if the recombinant protein was prepared for use in humans, such a modification could lead to reduced efficacy of the antigenic material itself and might elicit cross-reactive autoimmune responses. These inhibitors might also interfere with protein crystallization, especially if the modifications are at contact points in the crystal lattice. Furthermore, modified proteins could display multiple spots on two-dimensional gel-electrophoretic analysis, that is, spots with the same molecular size but varying pH.

Soon after cell breakage, EDTA is added to the lysed cell suspension to 5 mM to chelate Mg²⁺, which could cause protein aggregation(12) to activate metalloproteases and to accelerate protein oxidation.

### 2.1.2 Clarification of the Extract

Following cell disruption by chemical or mechanical procedures, intact cells and residual cell debris are removed by centrifugation at 3000 g for 30 min. The supernatant fraction is then subjected to ultracentrifugation at 150,000 g for 2 h to sediment cell envelopes. Pellets are usually resuspended in BB with magnetic stirring and the distribution of the protein of interest is assessed by sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE) analysis. If the recombinant protein is soluble, most of it should be present in the 150,000 g supernatant. If it is found in the 3000 g pellet, it is an indication that the recombinant protein is present in inclusion bodies. Solubilization and refolding of recombinant proteins from inclusion bodies is covered in sections 2.2 and 2.3.

### 2.1.3 Choosing Assays for Protein or Biological Activity

It is important to be able to assay for the protein of interest early in the purification. The presence of a prominent band on a sodium dodecyl sulfate (SDS) gel might not be enough. I know of cases where investigators purified a protein by following a fat band on SDS gels. After the protein had been crystallized and its structure had been determined, it was realized that they had purified an *E. coli* protein whose structure...
was already known. If antibody is available the protein can be followed by immunoblotting,

\[13\] if it is an enzyme, by its enzymatic activity; if it is a receptor, by ligand binding. Amino acid analysis, N-terminal amino acid sequencing or most conveniently in-gel proteolytic digestion followed by matrix-assisted laser desorption ionization/mass spectrometry (MALDI/MS) analysis

\[14\] can also provide us with a positive identification. The biological activity divided by the total amount of protein present yields the specific activity of the assayed protein. These measurements should be routinely performed during the purification train in order to assess the efficiency of each purification step.

2.1.4 Differential Solubility Techniques

Fractionation of complex protein mixtures using organic solvents, mainly ethanol and acetone, was widely used in the early days of protein purification. More recently, these reagents are being displaced by poly(ethylene glycol) (PEG) and ammonium sulfate. Organic solvents destabilize proteins, whereas PEG and ammonium sulfate stabilize them, thereby minimizing losses of biological activity. If it is necessary to interrupt purification, then storing samples as ammonium sulfate suspensions perhaps could provide us with optimum conditions. Montoya and Castell

\[15\] studied the long-term storage of peroxidase-labeled immunoglobulins for use in enzyme immunoassays. Conjugates were stored at various temperatures (−40, +4, +25, +37°C) in liquid form in the presence of 50% glycerol, lyophilized or as ammonium sulfate precipitates. They evaluated the immunological and enzymatic activities of the conjugates at regular intervals. The best results were obtained with the conjugates stored in ammonium sulfate at 4°C. Under these conditions they estimated that the half-life of the conjugates was 9 years.

We routinely subject the 150 000 g supernatant to stepwise ammonium sulfate fractionation. Solid ammonium sulfate is added to 30% saturation, according to the table provided by England and Seifter.

\[16\] The suspension is stirred until the ammonium sulfate is dissolved and incubated on ice for 30 min. The precipitate formed is removed by centrifugation at 18 000 g for 20 min. The volume of the supernatant is measured and more ammonium sulfate is added to 50% saturation. The precipitate formed is pelleted as above and the supernatant fraction is brought to 80% saturation with respect to ammonium sulfate. The suspension is stirred and left on ice for 30 min. Precipitated proteins are pelleted and the distribution of proteins in the three ammonium sulfate pellets is determined by SDS/PAGE analysis. We usually pellet 200–500 µL of each ammonium sulfate suspension separately for SDS/PAGE analysis and the bulk of the ammonium sulfate pellets are kept at 4°C until the analysis is complete.

Ammonium sulfate precipitation has a high capacity but low resolving power; nevertheless, it not only serves as a crude enrichment step for the protein of interest but can also separate fibrous host proteins that have a tendency to polymerize with time and to clog membrane filters and chromatography columns. A word of caution is warranted here. Although most proteins are stable for long periods even in saturated ammonium sulfate, we have encountered some recombinant proteins (e.g. recombinant human retinoic acid receptor-γ, expressed in E. coli) that could not be resolubilized, after exposure to 80–100% saturated ammonium sulfate, in an aqueous buffer in which it was previously freely soluble. The same protein, however, could be resolubilized when it was exposed to 50–60% saturated ammonium sulfate.

The pH of a saturated ammonium sulfate solution is close to 5 and it should be neutralized with NaOH or aqueous ammonia before use.

2.1.5 Medium- and High-resolution Chromatographic Techniques

From Table 2, it is clear that of the common isolation and purification methods, chromatography provides us with the highest purification capability. The ammonium sulfate

fraction that contains most of the desired recombinant protein is therefore subjected to chromatographic fractionation. At first a pilot chromatographic experiment is performed manually for column selection, using small (2-mL) disposable columns packed with various gels. We routinely test six different chromatography matrices (Table 3); many others, of course, could be included, such as various immobilized dye–ligand adsorbents. (17) Each column, and the sample to be applied to that column, is equilibrated in an appropriate buffer (Table 3). The sample is applied and the column is washed with loading buffer. The first 5 mL of flow-through material is saved to represent the unbound fraction. The column is washed with an additional 10 column volumes of loading buffer and the bound molecules are eluted by washing the column with elution buffer. Ten 0.5-mL fractions are collected. Volumes of 10 μL of each fraction are spotted on to nitrocellulose membranes and the membranes are stained for 5 min in a solution of 0.1% aniline blue, prepared in methanol–acetic acid–water (5:1:5). The membranes are then destained in the same solution, without the dye. This allows us to determine quickly the fractions that should be analyzed by SDS/PAGE. The distribution of the target protein in the bound and unbound fractions permits us to make decisions concerning a purification train. The advantage of this approach over a “blind” column selection is that it allows us to predict not only the type but also the order of column use (Figure 1), thereby reducing the number of manipulations that would be required.

TRIS, tris(hydroxymethyl)aminomethane.

Figure 1 Pilot chromatographic experiment for column selection. An ammonium sulfate fraction of a total E. coli cell extract, containing a recombinant protein (**) (lane b) was applied to six different columns [Ceramic Hydroxyapatite (c, d), Phospho-Ultrogel® (e, f), Heparin-Actigel™ (g, h), Source™ 30Q (i, j), Source™ 30S (k, l) and TSK® Phenyl 5PW (m, n)]. Flow-through (lanes c, e, g, i, k and m) and eluted fractions (lanes d, f, h, j, l and n) were subjected to Coomassie® Blue stained SDS/PAGE analysis. Lane a contains molecular weight standards. Ceramic Hydroxyapatite, which retains most of the contaminating host proteins (lane d), was chosen as the first column. The recombinant protein was not retained on this column (lane c). Source™ 30Q, which binds the recombinant protein (lane j), was chosen as the second column.
PEPTIDES AND PROTEINS

Figure 2 Purification of the recombinant protein described in Figure 1. The total cell extract (lane b) was subjected to two centrifugation steps. The 3000 g and 150 000 g supernatants are shown in lanes c and d, respectively. Lane e represents proteins precipitated between 30% and 60% ammonium sulfate saturation from the 150 000 g supernatant. Lanes f–h show purification after hydroxyapatite, Source™ 30Q and gel filtration chromatography, respectively. Lane a contains molecular weight standards.

could cause protein denaturation. By combining the specificity and discriminatory powers of the various chromatographic techniques, it is possible to isolate a single protein species from a heterogeneous mixture (Figure 2).

Before starting protein purification, it is important to review the protein’s physical and chemical properties. Knowledge of the size, isoelectric point and number of cysteine residues can greatly influence the choice of extraction and fractionation methods. To demonstrate, let us take a hypothetical case depicted in Figure 3(a) and (b). We would like to separate a mixture of two proteins, lysozyme and bovine serum albumin (BSA). Lysozyme, a basic protein, has a pI of 11, and BSA, an acidic protein, has a pI of 4.9. Proteins at their pI have a net charge of zero. At pH values above their pI they are negatively charged and below their pI they are positively charged. At pH 8 lysozyme would be positively charged (cationic) and would bind to a cation exchanger which is negatively charged. At pH 8 BSA would be negatively charged (anionic) and would bind to an anion exchanger which is positively charged.

Figure 3 Diagrammatic representation of the charge and binding properties of (a) a basic protein, lysozyme (pI = 11), and (b) an acidic protein, BSA (pI = 4.9). At pH values above their pI proteins are negatively charged and below their pI they are positively charged. At pH 8 lysozyme would be positively charged (cationic) and would bind to a cation exchanger which is negatively charged. At pH 8 BSA would be negatively charged (anionic) and would bind to an anion exchanger which is positively charged.

using a single cation-exchange chromatographic step at a pH of 8. At this pH glycosyltransferase was positively charged and bound to a cation exchanger whereas most of the E. coli proteins were negatively charged and were found in the unbound fractions (Figure 4, lane c).

Figure 4 Purification of a recombinant glycosyltransferase from E. coli cell membranes. Nonionic detergent extract (lane b) of E. coli cell envelope fraction was applied to a Source™ 30S column at pH 8. Unbound proteins (lane c) were washed through with loading buffer. Bound proteins were eluted with a linear NaCl gradient (lanes d–j). Lane a contains molecular weight standards.
The order of the various techniques is important and their consideration must be included in the overall strategy to reduce time spent on sample treatment. For example if most of the target protein is found in the 30–50% saturated ammonium sulfate pellet, then it could be resolubilized and applied directly on to a hydrophobic interaction chromatography (HIC) column in 25% saturated ammonium sulfate. Elution from the HIC column is performed by decreasing the ionic strength, which can make the eluted fractions suitable for application to an ion-exchange or an affinity column.

Of the various chromatographic techniques that are available to us (Table 2), affinity chromatography can provide us with the best isolation and purification capability. For this reason, many investigators, using genetic engineering methods, have added “tags” or “affinity tails” to the recombinant polypeptide chain to permit their purification in a simplified way. Recombinant proteins, containing protein A or G sequences, can be purified on immobilized immunoglobulin columns. Furthermore, after purification the affinity tag can be removed with enterokinase. Thiol-containing tails allow the covalent attachment of the tagged protein to thioltated matrices. Genetically engineered C-terminal polyarginine was used to make the fusion protein very basic and thereby to bind to a cation-exchange column under conditions where the majority of the host proteins were found in the flow-through fraction. Removal of the polyarginine tag with carboxypeptidase B and rechromatography resulted in a large change in the elution profile of the recombinant protein but not of the contaminants. Biotin tail has been used to purify biotin-tagged proteins on monomeric avidin resin.

Recombinant proteins fused to glutathione S-transferase (GST) can be purified on immobilized glutathione-Sepharose® 4B. Polyhistidines have been used extensively to tag recombinant proteins and to allow their purification by metal–chelate affinity chromatography. The list of various affinity tails is extensive and there is not enough space here to cover them all, so the purification of only two affinity tagged proteins,GST- and hexa-His-tagged fusion proteins, both expressed in E. coli, is described. The GST fusion protein contained a thrombin cleavage site to facilitate the removal of the tag by thrombin treatment.

2.1.5.1 Purification of Glutathione S-Transferase Fusion Proteins For purification of GST fusion proteins containing thrombin cleavage site, the 150 000 g supernatant is mixed with 50 mL (settled volume) of glutathione-Sepharose® 4B matrix (Pharmacia) and agitated by end-to-end rotation for 16 h at 4 °C. The binding capacity is about 5 mg of GST per milliliter of packed gel. The gel is then pelleted by centrifugation at 650 g for 5 min and resuspended in about 100 mL of wash buffer [50 mM HEPES, pH 8, containing 10% glycerol, 150 mM NaCl, 1 mM EDTA-Na2, 1 mM D, L-dithiothreitol (DTT) and 1% Triton X-100]. The gel is pelleted as above, resuspended in 100 mL of wash buffer and divided into six 50-mL centrifuge tubes. Each fraction is then underlayered with 25 mL of 10% sucrose, prepared in wash buffer. The tubes are centrifuged at 980 g for 20 min and the gel is washed four times with wash buffer, once with wash buffer containing 0.5 M NaCl, and with wash buffer again. A small aliquot of the gel suspension is treated with SDS sample buffer and analyzed by SDS/PAGE to estimate the amount of fusion protein adsorbed. The pelleted gel is resuspended in 50 mL of wash buffer containing thrombin (Sigma® T-3010) and incubated by end-to-end rotation for 2 h at room temperature. The amount of thrombin required can vary between 1 and 15 units per milligram of fusion protein, and should be determined for each recombinant protein (Figure 5a and b).

![Figure 5](image-url)  
Figure 5 Thrombin cleavage of a GST fusion protein incubated at room temperature with (a) 1 or (b) 3 units of thrombin for the indicated times. The cleaved recombinant protein (1) and the GST affinity tag (2) are indicated. Molecular weight standards are shown on the left.
cleavage, n-dodecyl-β-D-maltoside is added to the gel suspension to 0.15% to improve the recovery of the cleaved protein. The suspension is transferred into a column, the effluent is saved and the column is washed with about 50 mL of wash buffer supplemented with 0.15% of dodecyl maltoside. The effluent and the wash fractions are combined and dialyzed for 16 h at 4°C against 2 L of 25 mM TRIS–HCl, pH 8, containing 5% glycerol, 1 mM DTT and 1 mM EDTA. The dialysate is filtered through a 0.22-µm pore-size membrane (Millex®-GV, Millipore®) and applied to a 25-mL diethylaminoethyl (DEAE)-Sephacel® column (Sigma®). The column is washed with three column volumes of loading buffer to remove the detergents. Bound protein is then eluted by washing the column in the reverse direction with 500 mM sodium phosphate buffer, pH 8, containing 10% glycerol. This chromatographic step removes residual detergents and also concentrates the cleaved recombinant protein and allows its direct application to a gel filtration column for final polishing (see section 2.1.8).

2.1.5.2 Purification of Poly-histidine-tagged Proteins

Immovlized metal chelate affinity chromatography was first introduced in 1975 and it has become a widely used technique. Originally the chelating ligand iminodiacetic acid (IDA), charged with Ni²⁺ or Zn²⁺, was used to purify various peptides and proteins. Since IDA has only three chelating sites, it does not bind metal ions strongly and allows its direct application to a gel filtration column for final polishing (see section 2.1.8). The affinity of hexa-His-tagged proteins to NTA is 1000 times higher than to IDA, which allows its use in strong denaturants such as 6 M guanidine–HCl, 8 M urea or high concentrations (1 M) of chaotropic salt solutions. This permits the use of highly stringent washing conditions to remove nonspecifically bound host proteins. The purification of recombinant hexa-His-tagged proteins under denaturing conditions was described in an earlier publication, and here a nondenaturing purification method for a hexa-His-tagged recombinant bacterial protein is presented.

NTA–agarose resin (Qiagen) is provided derivatized with Ni²⁺. Nevertheless, we usually go through the following preparation steps: Ni²⁺–NTA–agarose gel (50 mL) is washed in a column with 0.1 M NiSO₄, until NiSO₄ appears in the breakthrough. Excess Ni²⁺ is washed out with three column volumes of 0.1 M NaHPO₄, pH 6, containing 10% glycerol, 300 mM NaCl and 1% Triton X-100®. The column is then equilibrated in loading buffer (0.1 M NaHPO₄, pH 8, 10% glycerol, 300 mM NaCl, 1% Triton X-100®). The 150,000 g supernatant (see section 2.1.2) is made 1% with respect to Triton X-100® and filtered through a 0.22-µm pore-size membrane. The filtrate is mixed with the Ni²⁺-derivatized resin in a bottle and rotated for 1 h at room temperature. The suspension is transferred into a column and the effluent, representing the unbound fraction, is saved. The gel is washed with five column volumes of loading buffer, followed by five column volumes of loading buffer containing 5 mM β-mercaptoethanol. This washing step usually reduces background due to disulfide cross-linked proteins. Washing is continued with three column volumes of 0.1 M NaHPO₄, pH 6, containing 10% glycerol, 300 mM NaCl and 1% Triton X-100®, and three column volumes of the same buffer without Triton®. The recombinant protein is then eluted with five column volumes of a linear gradient of 500 mM imidazole–HCl, pH 6, containing 10% glycerol and 300 mM NaCl. The column is regenerated by washing with the elution buffer containing 100 mM EDTA-Na₂, until all the Ni²⁺ is eluted from the column. Washing is continued with 6 M guanidine–HCl, in 0.1 M sodium acetate buffer, pH 4, and the column is stored in 0.1 M NaCl–20% ethanol at 4°C. The gel can be derivatized with Ni²⁺ as described above and reused repeatedly.

2.1.6 The Final Steps

First we use less specific techniques of centrifugation, nucleic acid removal and protein precipitation. These are followed by high-resolution chromatographic methods such as ion-exchange, affinity and HIC. Gel filtration complements precipitation and the high-resolution methods, and it enables us to determine molecular size in a simple way. It is a very gentle purification method since there is no or little interaction of the protein with the gel matrix, and the whole separation is conducted in a constant buffer system. Gel filtration chromatography is usually used in the later stages as a final polishing step to remove the last traces of impurities, to separate multimer and aggregated forms of the protein from the monomers and to exchange into buffer systems suitable for assays, for crystallization or for formulation.

2.2 Purification of Proteins from Inclusion Bodies

Very often heterologous proteins, expressed in E. coli, are precipitated in the cells in the form of highly refractile inclusion bodies. Purifying recombinant proteins from inclusion bodies is similar to the isolation of soluble egg albumin from a hard-boiled egg. The presence of the recombinant protein of interest in the 3000 g pellet indicates that it is in inclusion bodies. Inclusion bodies fall into two categories: (1) paracrystalline type and (2) amorphous aggregates. Both contain most of the recombinant protein in a precipitated, denatured form. In addition to the recombinant protein, inclusion bodies also contain coprecipitated host proteins, especially proteins...
of the host translation and transcription machinery, and also nucleic acids. Originally it was thought that inclusion body formation was harmful and hindered purification of the protein of interest. In recent years many investigators have found the formation of inclusion bodies to be desirable since they can simplify protein purification. Inclusion bodies are usually washed with weak detergents and chaotropic agents to remove some of the host proteins. This can result in the enrichment of the recombinant protein to 65% or better.

### 2.2.1 Recovery of Inclusion Bodies

To purify recombinant proteins from inclusion bodies, the 3000 g pellet, after opening the cells, is resuspended in 50 mM TRIS–HCl buffer, pH 8, containing 10% glycerol, 2 mM EDTA, 0.1 mM DTT, 200 µg mL⁻¹ lysozyme and 2% NP-40 or 1% 3-[3-cholamidopropyl]dimethylammonio]-1-propanesulfonate (CHAPS), by homogenization. The inclusion bodies are pelleted by centrifugation at 12 000 g for 15 min and the extraction is repeated three more times. The pellet is resuspended in 20 mL of extraction buffer as above and layered on top of 50% glycerol (2 × 30 mL) and centrifuged at 12 000 g for 30 min. The inclusion body pellet is then washed free of detergent by two cycles of resuspension in 50 mM TRIS–HCl buffer, pH 8, and centrifugation at 12 000 g for 15 min.

### 2.2.2 Solubilization of Inclusion Body Protein

The washed inclusion bodies are then solubilized in 20 mL of 7 M urea in 25 mM TRIS–HCl buffer, pH 8, containing 100 units mL⁻¹ Trasylol®, 5 mM e-aminocaproic acid, 10% glycerol, 1 mM EDTA and 10 mM lysine or 10 mM ethylenediamine. Lysine or ethylenediamine is included whenever urea is used as a scavenger of amine-reactive cyanates originating from the breakdown of urea. Cyanate ions can react with amino groups of proteins to form carbamylated derivatives. The solution is stirred at room temperature for 30 min and centrifuged at 150 000 g for 1 h. The supernatant is filtered through a 0.22-µm pore-size membrane and applied to a 50-mL Source 30Q column, equilibrated in solubilization buffer. Unbound proteins are washed out with solubilization buffer and bound components are eluted with 10 column volumes of a linear gradient of 0 to 1.0 M NaCl in solubilization buffer. Fractions are collected and location and purity of the recombinant protein are assessed by SDS/PAGE analysis. Depending on the purity of the recombinant protein in question, an additional purification step, for example gel filtration, can be performed or the denatured protein may be refolded by one of the methods described below.

### 2.3 Refolding of Inclusion Body Proteins

There are many published refolding methods and there is no single method that would be applicable to all proteins. The denaturant used to solublize inclusion bodies must be removed to allow refolding of the protein. The recovery of activity depends on the formation of correct intramolecular interactions including disulfide bonds. The principal change that is being reversed is not chemical but physico-chemical, involving noncovalent and conformational changes. The refolding methods usually consist of either chaotrope-mediated folding, cosolvent-assisted folding, detergent-mediated folding, chaperone-assisted folding or a combination of these methods. Strict guidelines to refold proteins cannot be given since the requirements are protein specific, but the general consensus is as follows: (1) during refolding the protein concentration must be low, <0.5 mg mL⁻¹ or preferably <0.1 mg mL⁻¹, in order to favor intramolecular interactions in preference to intermolecular interactions; (2) expose recombinant proteins to alkaline pH (pH > 9.0) in the presence of thiol reagents, 50 mM DTT or 0.1 M β-mercaptoethanol, and a denaturant, 8 M urea or 6 M guanidine–HCl, to solubilize aggregates; the use of DTT over mercaptoethanol is preferred since it does not form mixed disulfides with proteins, as mercaptoethanol does; (3) slow removal of the denaturant by dialysis or preferentially by dialysis at around 10 °C; (4) the inclusion of several additives in the dialysis buffer, 0.01% Triton X-100®, 0.4–0.5 M L-arginine, 5 mM EDTA, 25% glycerol, 150–200 mM KCl; and (5) the presence of redox reagents such as reduced (4 mM) and oxidized (0.4 mM) glutathione to promote disulfide shuffling. The number of ways in which cysteine residues can combine to form disulfide bonds increases very rapidly with increase of the number of cysteines. The recombination protein human tissue plasminogen activator, for example, has 17 disulfide bonds. The 35 cysteine residues present in this protein theoretically can form disulfide bonds 2.2 × 10²⁰ ways. If disulfide bond formation were to occur at random, then statistically one would need 200 000 tons

</table>
of inclusion body protein to correctly refold 1 ng of this protein. However, luckily for us, in a real-life situation refolding is biased towards the formation of the correct three-dimensional structure. This is an important piece of information because it means that the three-dimensional functional state of a folding protein is more stable than the unfolded state. This thermodynamic statement underlies all our efforts to refold proteins. Over millions of years nature has selected for those proteins that are most active in their most stable form.

Very rarely a denatured and reduced protein will refold to a soluble and active form by simple dialysis against a physiological buffer to remove the denaturant. A relatively simple protocol was sufficient to refold the recombinant protein, expressed in *E. coli*, and shown in Figure 6(a). After washing of inclusion bodies, solubilization and purification of the recombinant protein on a Source™ 30Q anion-exchange column, the denaturant (7 M urea) was removed by dialysis against 10 mM sodium phosphate buffer, pH 6.8, containing 2 mM dodecyl maltoside. Dialysis was continued against 25 mM HEPES–NaOH, pH 8, containing 50 mM NaCl. The refolded protein was concentrated by dialysis against 4 M ammonium sulfate, centrifuged, the pellet dissolved in 50 mM HEPES–NaOH, pH 7.8, containing 150 mM NaCl. The solution was filtered through a 0.22-µm pore-size membrane and subjected to gel filtration chromatography on a Superdex™ 200 (2.6 × 60 cm) column in the same buffer.

Figure 6(b) shows SDS/PAGE analysis of fractions eluted from this column. The refolded protein was active and chromatographed as a monomer on the gel filtration column. More often, however, we have to “guide” an unfolded protein through a series of conformational states to allow refolding. This is usually done by subjecting the denatured and reduced protein to high concentration of labilizing agents such as 0.5 M L-arginine or lysine. At the concentration used these basic amino acids are perturbents and destabilizers of structure. However, they are not strong enough to destabilize correctly folded polypeptides. They allow the reshuffling of the less stable misfolded molecules being trapped in side reactions. In our laboratory we had good experience with the following refolding protocol: the purified inclusion body protein is diluted to 50–100 µg mL⁻¹ with the 7 M urea buffer described above for the solubilization of inclusion bodies. The diluted protein is dialyzed against 3 × 2 L of refolding buffer (25 mM glycyglycine–HCl, pH 9.5, containing 0.4 M L-arginine, 0.5 M NaCl, 1 mM EDTA, 25% glycerol, 4 mM reduced glutathione and 0.4 mM oxidized glutathione) for 3 days at 10°C. Dialysis is continued against 2 × 2 L of 20 mM glycyglycine–NaOH, pH 9, containing 25% glycerol, 150 mM NaCl, 1 mM EDTA, 0.01% Triton X-100® and 50 mM (NH₄)₂SO₄.
buffer for 2 days at 10°C. The dialyze is centrifuged at 48,000 g for 30 min and the supernatant is filtered through a 0.22-μm pore-size membrane and concentrated to 1–5 mg mL⁻¹ using either a stirred cell (Amicon) or a tangential-flow device (Millipore®). The buffer is usually exchanged for 20 mM glycylglycine–NaOH, pH 9, containing 5% glycerol, 1 mM EDTA and 150 mM NaCl, using a PD-10 column (Pharmacia). Refolding is monitored by activity measurements and by gel filtration chromatography to assess the amount of monomers and multimers in the preparation.

In Figure 7(a) and (b) the refolding of recombinant Staphylococcus aureus DNA gyrase B fragment, expressed in E. coli, is shown. Dialysis of urea solubilized protein against 20 mM TRIS–HCl, pH 8.3, 50 mM NaCl buffer resulted in the formation of about 50% of aggregated forms of the protein as revealed by gel filtration on a Superdex™ 200 column (Figure 7a). However, subjecting the protein to the refolding protocol described above resulted mainly in monomers (Figure 7b).

3 PURIFICATION OF NATIVE INTRINSIC MEMBRANE PROTEINS FROM MAMMALIAN CELLS

The cell membrane not only functions as a permeability barrier but is also the site of a number of specific enzymes and other proteins that play a role in cell recognition and interaction and in the multitude of specific transport processes. Biological membranes are composed of lipids and proteins to which carbohydrate may be covalently bound. According to the model of Singer and Nicolson, the membrane is fluid or dynamic and the proteins are swimming in or on the viscous lipid bilayer. Lipids, which constitute almost half of the plasma membrane mass, not only serve as an anchoring medium for membrane proteins but also may be responsible for the activity of membrane-associated enzymes. Lipids are amphipathic, having hydrophilic and hydrophobic ends. The majority of the membrane lipids are phospholipids, the rest being made up of glycolipids and neutral lipids, mainly cholesterol. The glycolipids are restricted to the outer half of the lipid bilayer, indicating that an asymmetry exists between the two leaflets of lipid layers. This asymmetry is also evident when we examine the distribution of membrane proteins. Most, if not all, of the intrinsic membrane proteins are glycosylated and have their carbohydrate moieties on the non-cytoplasmic side of the membrane. Proteins that are directly or indirectly associated with the lipid bilayer are frequently differentiated into three groups depending on whether they are (1) artificially adsorbed or are a (2) peripheral (extrinsic) or (3) integral (intrinsic) part of the membrane. Before the purification of intrinsic membrane proteins can be undertaken, they must be extracted from the membrane matrix. For this purpose one might employ urea, EDTA, distilled water, organic solvents, controlled proteolysis, guanidine and other chaotropic agents or manipulation of ionic strength and pH. These methods, however, do not lead to the complete solubilization of proteins that are strongly bound to the lipid matrix of the membrane. For intrinsic membrane proteins, detergents (synthetic detergents, bile salts and saponins) appear to provide the best extraction method. There are many detergents available for the solubilization of membrane proteins. The detergent of choice should be able to disintegrate the membrane and keep the proteins in solution without destroying the protein’s antigenic structure, thereby interfering with antigen–antibody interactions. Neutral or nonionic detergents fulfill these requirements. Of the many neutral detergents that have been employed for membrane solubilization, we prefer NP-40 [poly(ethylene glycol) p-isooctylphenyl ether] for the solubilization of lymphocyte plasma membranes. NP-40 is a relatively mild, yet highly effective solubilizing agent for membrane proteins.

At the concentration used, 0.5%, it reacts mainly with the hydrophobic, lipophilic portions of proteins without interfering with antibody interactions directed at the hydrophilic portions of cell surface antigens. Furthermore, at this concentration NP-40 does not solubilize nuclear membranes, an important consideration when detergent extraction of intact cells is undertaken.

Optimum conditions for solubilization with neutral detergents include the use of low ionic strength buffer (<0.2 M), alkaline pH (8–8.5), a detergent to protein ratio of at least 1.5 and a protein concentration below 3 mg mL⁻¹. Since the degree of solubilization is only slightly influenced by temperature, solubilization should be done at 0°C to reduce proteolytic degradation of membrane proteins. Enzymatic degradation of the solubilized proteins can be a serious problem and many investigators include a cocktail of protease inhibitors in the solubilization mixture.

For the purification of membrane proteins one may solubilize whole cells with detergents. However, since the plasma membrane proteins represent only about 1% of the total cellular proteins, it is an advantage to prepare membranes first. Purified membranes represent approximately a 50-fold purification of cell surface antigens.

3.1 Preparation of Sub-cellular Fragments

Large-scale purification of plasma membranes is best achieved by nitrogen decompression of cell suspensions, followed by differential centrifugation of the resulting

PROTEIN PURIFICATION: THEORETICAL AND METHODOLOGICAL CONSIDERATIONS
homogenate. If possible, the use of established cell lines is recommended for the purification of cell surface antigens. Cultured cell lines provide a uniform and continuous source of antigens.

Cells (5 × 10^7 – 1 × 10^8) are washed twice with BB (20 mM HEPES, pH 7.5, containing 0.13 M NaCl, 0.5 mM MgCl₂ and 1 mM PMSF) by centrifugation at 800 g for 10 min. Cell pellets are resuspended in 10^7 cells mL⁻¹ in BB and an equal volume of 0.5 M sucrose is added with constant gentle agitation. The cell suspension is equilibrated with nitrogen gas in a Parr nitrogen cavitator (Parr® Instruments) for 15 min at 50 atm (5.07 MPa) at 0–4 °C. Cell breakage is achieved by dropwise release of the cell suspension. EDTA is added to a 1 mM final concentration and the homogenate is fractionated by differential centrifugation. Nuclei, unbroken cells and debris are removed by centrifugation at 800 g for 15 min. The supernatant is centrifuged at 20 000 g for 20 min to pellet mitochondria and lysosomes. Membrane vesicles in the supernatant are then pelleted by centrifugation at 120 000 g for 60 min. Pelleted membranes are washed consecutively with 10 and 1 mM HEPES, pH 7.5. For most experiments these membranes may be used without further purification. However, they may be further separated into plasma membrane and endoplasmic reticulum by isopycnic centrifugation through discontinuous Ficoll gradients. The gradient is prepared from 35, 25, 17.5, and 9% Ficoll in 1 mM HEPES, pH 7.5, representing specific gravities of 1.12, 1.09, 1.06 and 1.03 g cm⁻³, respectively, on top of a 70% sucrose cushion. After centrifugation at 30 000 g for 2 h at 4 °C the plasma membrane banding at a density of 1.06 is removed and washed with 20 mM HEPES, pH 7.4, by centrifugation at 140 000 g for 60 min.

3.2 Solubilization of Cell Membranes

Cell surface proteins may be directly solubilized at a cell density of 2 × 10³ mL⁻¹ on ice for 30 min in 1% NP-40 in phosphate-buffered saline (PBS) (0.02 M sodium phosphate, pH 7.8, 0.15 M NaCl, 1 mM MgCl₂, 0.5 mM CaCl₂) containing 1 mM iodoacetamide, 1 mM PMSF and 10 µg mL⁻¹ of each of the protease inhibitors listed above, at 0 °C for 30 min with magnetic stirring. The extract is centrifuged at 150 000 g for 60 min. If not immediately used, detergent extracts should be stored at −70 °C.

3.3 Immunoaffinity Purification of Membrane Proteins

For the purification of immunoaffinity columns, antibodies may be immobilized directly to CNBr-activated Sepharose® (Pharmacia) or to activated gels that contain spacer arms, e.g. Affi-Gel® 10 (Bio-Rad), according to the manufacturer’s instructions. A spacer arm is used to keep the antibody away from the gel matrix so that the combining site of the antibody molecule is free to bind the antigen. Perhaps the best immunoadsorbent to purify membrane proteins is prepared by oriented coupling of antibodies through their Fc portions to immobilized protein A or protein G resins with the bifunctional cross-linking reagent dimethyl pimelimidate. Protein A-Sepharose® CL-4B (Pharmacia) or protein G–agarose (Oncogene®, No. IP08) is mixed with the antibody solution in 0.1 M borate buffer, pH 8.2, at about 10 mg antibody per milliliter of packed beads. The slurry is rotated at room temperature for 60 min, transferred into a sintered glass filter and washed extensively with 0.1 M borate buffer, pH 8.2, followed by washing with 0.2 M triethanolamine–HCl, pH 8.2. The gel is transferred to a tube with about 25 volumes of 0.2 M triethanolamine, 50 mM dimethyl pimelimidate dihydrochloride (Pierce), pH 8.2. The tube is rotated for 45 min and the gel is centrifuged and treated with a fresh aliquot of cross-linking solution as above for another 45 min. After this incubation time, the gel is centrifuged and resuspended in 25 volumes of blocking buffer (50 mM ethanolamine–HCl, pH 8.2, 0.15 M NaCl), and incubated at room temperature for 30 min. Finally, the gel is washed twice with 0.1 M borate buffer, pH 8.2, and stored at 4 °C in the presence of 0.02% sodium azide.

For the immunoaffinity purification of intrinsic membrane proteins, detergent extracts obtained either from solubilized whole cells or from purified membranes are applied using a recycling system (peristaltic pump) to two successive columns attached in series, containing (1) immobilized nonspecific mouse mAb, and (2) a specific mouse mAb column recognizing the desired antigen. The precolumn is used to remove components from the lysates that bind nonspecifically either to the gel matrix or to the immobilized antibodies.

The specific antibody column is usually prewashed with elution buffer (50 mM diethylamine–HCl, pH 11.5, 1% n-octyl-β-D-glucopyranoside (OG), 150 mM NaCl, 1% 40 in phosphate-buffered saline (PBS) (0.02 M sodium phosphate, pH 7.8, 0.15 M NaCl, 1 mM MgCl₂, 0.5 mM CaCl₂) containing 1 mM iodoacetamide, 1 mM PMSF and 10 µg mL⁻¹ of each of the protease inhibitors listed above, at 0 °C for 30 min with magnetic stirring. The extract is centrifuged at 150 000 g for 60 min. If not immediately used, detergent extracts should be stored at −70 °C.

3.3 Immunoaffinity Purification of Membrane Proteins

For the preparation of immunoaffinity columns, antibodies may be immobilized directly to CNBr-activated Sepharose® (Pharmacia) or to activated gels that contain spacer arms, e.g. Affi-Gel® 10 (Bio-Rad), according to the manufacturer’s instructions. A spacer arm is used to keep the antibody away from the gel matrix so that the combining site of the antibody molecule is free to bind the antigen. Perhaps the best immunoadsorbent to purify membrane proteins is prepared by oriented coupling of antibodies through their Fc portions to immobilized protein A or protein G resins with the bifunctional cross-linking reagent dimethyl pimelimidate. Protein A-Sepharose® CL-4B (Pharmacia) or protein G–agarose (Oncogene®, No. IP08) is mixed with the antibody solution in 0.1 M borate buffer, pH 8.2, at about 10 mg antibody per milliliter of packed beads. The slurry is rotated at room temperature for 60 min, transferred into a sintered glass filter and washed extensively with 0.1 M borate buffer, pH 8.2, followed by washing with 0.2 M triethanolamine–HCl, pH 8.2. The gel is transferred to a tube with about 25 volumes of 0.2 M triethanolamine, 50 mM dimethyl pimelimidate dihydrochloride (Pierce), pH 8.2. The tube is rotated for 45 min and the gel is centrifuged and treated with a fresh aliquot of cross-linking solution as above for another 45 min. After this incubation time, the gel is centrifuged and resuspended in 25 volumes of blocking buffer (50 mM ethanolamine–HCl, pH 8.2, 0.15 M NaCl), and incubated at room temperature for 30 min. Finally, the gel is washed twice with 0.1 M borate buffer, pH 8.2, and stored at 4 °C in the presence of 0.02% sodium azide.

For the immunoaffinity purification of intrinsic membrane proteins, detergent extracts obtained either from solubilized whole cells or from purified membranes are applied using a recycling system (peristaltic pump) to two successive columns attached in series, containing (1) immobilized nonspecific mouse mAb, and (2) a specific mouse mAb column recognizing the desired antigen. The precolumn is used to remove components from the lysates that bind nonspecifically either to the gel matrix or to the immobilized antibodies.

The specific antibody column is usually prewashed with elution buffer (50 mM diethylamine–HCl, pH 11.5, 1% n-octyl-β-D-glucopyranoside (OG), 150 mM NaCl, 1% 40 in phosphate-buffered saline (PBS) (0.02 M sodium phosphate, pH 7.8, 0.15 M NaCl, 1 mM MgCl₂, 0.5 mM CaCl₂) containing 1 mM iodoacetamide, 1 mM PMSF and 10 µg mL⁻¹ of each of the protease inhibitors listed above, at 0 °C for 30 min with magnetic stirring. The extract is centrifuged at 150 000 g for 60 min. If not immediately used, detergent extracts should be stored at −70 °C.
PROTEIN PURIFICATION: THEORETICAL AND METHODOLOGICAL CONSIDERATIONS

1 mM EDTA, 1 mM iodoacetamide) and both columns are equilibrated in wash buffer 1 (50 mM TRIS–HCl, pH 8, 150 mM NaCl, 0.5% NP-40, 0.5% DOC, 10% glycerol), before application of the detergent extracts. After recirculation of the extract through both columns (2–3 times), the precolumn is removed and the specific immunoaffinity column is washed with about 20 column volumes of wash buffer 1. This is followed by a wash with five column volumes of wash buffer 2 (50 mM TRIS–HCl, pH 9, 500 mM NaCl, 0.5% NP-40, 0.5% DOC, 10% glycerol). This high-pH and high-salt wash will elute a lot of nonspecifically adsorbed components. The column is then washed with five column volumes of wash buffer 3 (2 mM TRIS–HCl, pH 8, 1% OG, 10% glycerol). This washing step exchanges the detergents for the dialyzable OG and reduces the ionic strength of the buffer in preparation for elution. Bound antigen is then eluted by washing the column with elution buffer (described above). From a 5-mL immunoaffinity column we usually collect 2-mL fractions into tubes that contain 250 µL of 1 M TRIS–HCl, pH 6.8, 0.15 M NaCl and 1% OG, in order to neutralize the pH. Figure 8 shows the immunoaffinity purification of HLA-DR1 molecules from a human lymphoblastoid cell line.

4 SUMMARY

The biotechnological revolution of the past 20 years has given a strong impetus to interest in methods for the separation and purification of proteins. Purified proteins are needed in several steps during the drug development process: (1) for development of assays; (2) for crystallization of apo- and holo-forms of the protein; (3) for high-throughput screening; and (4) as drugs themselves. Purification protocols are also used for the fractionation and enrichment of low-copy-number proteins in order to facilitate proteome analysis. Recent developments in chromatographic separation methods, in two-dimensional polyacrylamide gel technology and large-scale sample throughput mass spectrometry now allow us to prepare master purification steps. Complex protein mixtures of entire organisms are being separated by chromatographic methods, the protein content of the resolved fractions are analyzed by two-dimensional polyacrylamide gel electrophoresis and the proteins present are identified by mass spectrometry. Such master schemes will become valuable tools in the isolation of many known or hypothetical proteins.

With advances in DNA technology it became possible to express large amounts of virtually any protein in various host cells. In fact, the technology for cloning genes for a magnitude of proteins has developed at a faster rate than the technology for purifying the expressed gene products. In this article we have covered some basic procedures for the purification of soluble recombinant proteins expressed in E. coli and methods to obtain soluble and active protein from insoluble and inactive inclusion bodies. As a first step the protein of interest has to be released into an aqueous extract. Following extraction, residual debris and intact cells are removed by centrifugation. Nucleic acids are either hydrolyzed or precipitated to reduce the viscosity of the extract. A crude enrichment for the protein of interest is made based on its differential solubility in ammonium sulfate. This is then followed by high-resolution chromatographic methods. The type of chromatographic matrices and the order of their use are evaluated in pilot experiments for column selection. Gel filtration chromatography is used as a final polishing step to remove last traces of impurities and to separate multimer and aggregated forms of the protein from the monomers.

In the last section, the purification of a native intrinsic membrane protein, using immobilized mAbs, was also covered. The use of immunoaffinity purification of integral membrane proteins is emphasized since specific mAbs may be obtained even against low-copy-number membrane proteins by reducing a multispecific antibody response to a series of monospecific responses by cloning. The use of immobilized, highly specific mAbs should allow the purification of many minor and weakly antigenic membrane proteins that might be missed by other methods.
The rapid identification of proteins using peptide mass fingerprinting provides us with a continuously expanding number of new potential therapeutic targets. For many of these proteins we do not even have a biological function. In order to understand the molecular mechanisms in which they are involved, these proteins will have to be purified and characterized. The cataloging of the total protein content of various organisms is progressing rapidly. The existence of a functional protein blueprint would be invaluable not only for the diagnosis but possibly also for the treatment of many diseases.

ACKNOWLEDGMENTS

The author acknowledges the invaluable technical assistance and efficient secretarial help of Marie-Françoise Takács and thanks Dr Michael Fountoulakis for reading the manuscript. The author is also indebted to Dr Paul Hadváry, without whose understanding these studies would not have been possible.

PROTEIN PURIFICATION: THEORETICAL AND METHODOLOGICAL CONSIDERATIONS

Noncovalent (reversible) drug–protein binding interactions are an integral part of intermolecular recognition processes taking place in a cell or organ environment. Characterization of basic constraints of target protein binding site(s) (affinity, stoichiometry, specificity, saturability and stereoselectivity) for particular ligand(s) is an essential output of many different drug–protein binding studies. Nonlinear and stereoselective binding phenomena, including drug–drug (or enantiomer–enantiomer) interactions and their e.g. genetically or pathophysiological determined variability, can be predicted in this way. In general, the methods used for drug–protein binding studies can be divided into separation (nonspectroscopic) and spectroscopic methods. Separation methods are particularly suitable for the quantitative determination of drug binding, whereas spectroscopic techniques are able to characterize the qualitative features of drug–protein complexes (e.g. conformational status/changes). The primary objective was to summarize the most relevant trends in separation techniques [affinity high-performance liquid chromatography (HPLC) and affinity capillary electrophoresis (ACE)] employed in the framework of drug–protein/biopolymer binding assays and to compare them with so-called conventional approaches (equilibrium dialysis (ED), ultrafiltration). Focused attention has been paid particularly to HPLC and capillary electrophoresis (CE) methods designed for drug–protein studies when so-called “dynamic” and “secondary” equilibria are involved and created. A common feature of this strategy is to use binding protein(s) or interacting drug(s) without their covalent immobilization as mobile phase or background electrolyte (BGE) (buffer) additives. This offered a new, elegant tool for the separation of “bound” and “free” forms of interacting species in a “miniaturized free solution system” operating under nearly physiological conditions. Undoubtedly, it permits simplification of the experimental protocols where it is crucial to perform repetitive analyses under “the same starting conditions”, as e.g. the occupancy of binding sites is concerned.

1 INTRODUCTION

Drug–protein interactions are an integral part of intermolecular recognition and/or mediating processes taking place in cells or tissues of a living organism, including transport phenomena through membranes. In the recent decades, implementation of advanced methodological tools has enabled a competent and comprehensive insight to be obtained into various relevant aspects and operating mechanisms of drug binding to different functional, transport or depot proteins. Undoubtedly, there are many similarities encountered in the mechanisms of drug binding to proteins compared with protein–protein, protein–carbohydrate, protein–DNA, drug–DNA, enzyme–protein (peptide), etc., binding interactions. However, since most of them are primary subjects of other articles here, we shall just highlight the most relevant trends, particularly using examples on drug attachment to receptor and nonreceptor proteins. The availability of sophisticated analytical instrumentation and techniques facilitated the recognition of the complexity of interlocked biomolecular signaling networks after a drug/xenobiotic has entered the biological system and the resulting pharmacodynamic (toxicological) or pharmacokinetic impact in vivo.

Molecular topology of the most common “protein drug acceptors” (Table 1) suggests that interacting proteins

\(a\) Stereoselective binding of drugs has been considered and/or reported. FAA, free fatty acids; AGP, \(\alpha_1\)-acid glycoprotein.

are usually integrated in, for example, intra- or extracellular surfaces of membranes, building functional units of “true” receptors or “receptor-like” structures, ion channels or pumps. Only to a lesser degree are they available in matrix-soluble form (such as carbonic anhydrase in erythrocytes\(^{[8-10]}\) or well-known plasma drug transporters, albumin\(^{[25,26]}\) and AGP\(^{[16]}\)). There is clear evidence that at least some of the commonly applied purification or solubilization steps may cause subtle structural and/or steric changes of the protein binding site(s), resulting in profound, including stereoselective, differences in binding profiles of interacting drugs. Therefore, detailed knowledge of the conformational status and adaptability of “drug acceptors”, as well as preserving of integrity of their molecular environment (e.g. membrane, lipid or coupling proteins), is a critical point for the determination of “true”, molecularly plausible, binding affinities.

The essential output of drug–protein binding studies is to characterize at least some of the principal functional criteria of protein binding sites, i.e.:\(^{[27]}\)

- affinity;
- stoichiometry (i.e. monovalent vs multivalent binding);

• (species or tissue) specificity;
• saturability [i.e. presence of eventual nonlinear binding phenomena;\(^{(28,29)}\)]
• stereoselectivity.

More specifically, relevant information on drug–drug (or enantiomer–enantiomer) interactions\(^{(30–34)}\) and their, for example, genetically\(^{(17,35)}\) or pathophysiologically\(^{(16,36–38)}\) determined variability has to be elucidated frequently. End-points of many binding studies include understanding of the complex biological impact of drug–protein or protein–protein interactions at the cellular or subcellular level (i.e. interlinking, “on–off” or “tuning” effect).

All of the above-mentioned aspects have to be reflected by using an appropriate analytical/experimental methodology providing an objective and reliable picture of the situation in vivo or in vitro. Table 2 summarizes the fulfillment of the most relevant criteria when different approaches are adapted for evaluation of the various aspects of binding interactions. The following sections of this article outline on a comparative basis the balance between potential advantages and limitations of different methods and their combinatorial potential and/or complementary features.

2 MOST RELEVANT CHARACTERISTICS OF DRUG–PROTEIN BINDING ASSAYS

2.1 Binding Stoichiometry
Information on the stoichiometry of biomolecular interactions not only implicates their specificity, but also enables one to gain an insight into the network of interlinked molecular mechanisms inevitable for a living organism [regulation of programmed cell death, polyclonal humoral immune response or bacterial resistance.\(^{(39,40)}\)] This holds true particularly for multivalent recognition, stemming from association of multiple complementary ligands with multiple binding sites of receptors, acceptors or their dimers/oligomers. The situation, which has to be analyzed in case of relatively transparent bivalent binding, is depicted schematically in Figure 1. The most common problems concerning the derivation of binding data are further outlined in section 5. Taking into account possible interfering factors (e.g. generation of intermediates in the course of tight vs weak binding attachments), the methodological approach used has to fulfill these specific demands or should be refined appropriately.\(^{(39–42)}\)

2.2 Binding Specificity
The specificity of drug–protein binding interactions is very variable, ranging from “multidrug transporters” such as P-glycoprotein\(^{(2–4,43)}\) or albumin\(^{(12,25,44)}\) to highly specialized drug carriers such as cyclophilin engaged in cyclosporin A transport\(^{(44)}\) or β-tubulin for Vinca alkaloid binding\(^{(45)}\) (further examples are listed in Table 1). Hence the characteristic spectrum of drug affinities for target functional proteins is capable of mediating, more or less selectively addressed, many recognition and transduction processes on a molecular level simultaneously. This implicates direct modulation of drug efficacy and toxicity in target tissues.

Drug binding properties may differ considerably among the species\(^{(46–49)}\) [interspecies differences have been described in detail particularly for drug binding sites of albumins (Figure 2)\(^{(50)}\)], and any extrapolation of preclinical drug binding data should be done carefully. Similarly, pathophysiologically, genetically or artificially (in vitro) induced posttranslational modifications of proteins [e.g. tyrosylation, acetylation, glutamylation, phosphorylation of tubulin\(^{(45)}\), glycosylation of albumin\(^{(51,52)}\) or carbohydrate content of AGP\(^{(53)}\)] may alter the surface charges or hydrophobicity of the protein subunits, leading to profound changes in drug binding affinity and complicating the prediction of drug–drug interactions beyond those seen under normal conditions (i.e. in a healthy population).

2.3 Stereochemical Aspects
Chiral recognition properties of protein targets, distinguishing the three-dimensional conformation of an attaching pharmacophore, are responsible for quantitative or qualitative differences in affinity and/or efficacy of individual drug enantiomers.\(^{(54–56)}\) Thereby, stereospecificity is restricted to

• “true receptor sites”, including ion channels and other “receptor-like” structures;
2.4 Drug–Drug Binding Interactions

It is commonly known that competitive, displacement interactions at the same binding site as well as allosteric (non-primary site) drug–drug or enantiomer–enantiomer interactions may be revealed by testing for mutual interactions in binding assays. Allosteric influences may change the conformation of a receptor even if it is at some distance from the gating part of the channel. However, the conventional concept (i.e. Scatchard binding model) is no longer valid when allosteric binding phenomena are involved in the binding process. In some cases, competitive and allosteric binding interactions may undergo transformation into each other depending on the competitor’s concentration. Besides the more or less traditional views on drug−drug (enantiomer−enantiomer) displacement models, also cooperativity of binding sites as well as stereoselective “site-to-site” displacement of drug enantiomers have been considered. These findings underline further the importance of considering as well as different stereoselectivity toward interacting drugs.

From a pharmacokinetic point of view, intensive attention has been paid to stereoselective affinity differences of drug towards transport proteins acting as drug acceptors, transporters and storage targets in

- plasma (albumin and AGP);
- cell membranes with overexpression of specific proteins (P-gp);
- other compartments (e.g. isoenzymes of carbonic anhydrase in erythrocytes).

Of particular importance also are the chiral discriminative properties of cytochrome P450 isoenzymes, mediating stereoselective metabolic pathways. The enantiomeric ratios observed for transporters such as albumin or AGP rarely exceed a factor of 2 under physiological conditions. However, if saturation of binding sites can be approached or significant disease-induced changes in protein concentration are occurring, this situation could reach clinical significance. Of course, there are a number of further interfering factors that have to be taken into account for a final interpretation of the binding results and their overall pharmacological impact in vivo. Stereoselective interspecies binding differences, enantiomer−enantiomer (enantiomer−metabolite) interactions at binding sites, stereoselective covalent binding of metabolites, metabolic chiral inversion or racemization of the ligand or stereoselective cooperative binding of drugs represent the most important examples.

Only in a limited number of cases are the enantiomeric differences for a given drug similar for “receptor” and “acceptor” sites, suggesting that both binding targets may exhibit some degree of structural homology. Typically, the stereoselectivity is much more pronounced in the case of “receptor” than “acceptor” sites. As a rule, it increases with the affinity displayed towards the more tightly bound and pharmacologically more active enantiomer (eutomer) of a stereoisomeric pair. Apart from the “conventional receptor concept”, of particular pharmacodynamic interest is the interaction of chiral drugs with ion channels. The properties and access to the drug-binding site at channels termed “moving (dualistic) targets” may vary according to their different functional states (resting, open or inactivated) represented molecularly by different, dynamically changing conformations. Consequently, binding sites must be structurally rearranged as the channel changes its conformation. It therefore seems very likely that open and closed ion channels may have different (state-dependent) binding affinity

Figure 2: Interspecies binding differences: binding model proposed for drug binding sites on different albumins. Model binding drugs as depicted are warfarin (WF), phenylbutazone (PBZ), ibuprofen (IP) and diazepam (DZ), where WF and PBZ are markers of site I and IP and DZ are markers of site II. Human albumin site I appears to exist for rabbit and rat albumins, but not bovine albumin, and especially dog albumin. With respect to site II, both the binding constants and characteristics of IP and DZ are to dog albumin and are similar to human albumin, whereas the binding in other species is different, particularly the binding characteristics of DZ. (Reproduced with permission from Kosa et al.)

- “silent receptors” or “acceptors”, differentiating enantiomers without observing any obvious pharmacological response (Table 1).

3 METHODOLOGY OF BINDING EXPERIMENTS

3.1 Conventional Methods

Membrane separation methods, represented particularly by ED and ultrafiltration, have become very popular for the evaluation of drug binding to proteins owing to their simplicity and general applicability to many different systems in vitro and ex vivo. ED is based on the establishment of an equilibrium state between a “protein” compartment and “buffer” compartment which are separated by a membrane permeable only to low-molecular-weight components (i.e. drugs). On the other hand, ultrafiltration with semipermeable membranes produces a separation of the free/unbound drug by employing a chemical potential and pressure gradient, respectively, which forces the small drug molecules through the membrane. The possible interfering factors and potential shortcomings of ED and ultrafiltration as compared with ultracentrifugation, another conventional separation method, are summarized in Table 3. Although there is no declared “standard method” for the validation of binding data, ED is often regarded as the “reference method” for the determination of a drug–protein binding profile. In spite of this, ED suffers from a variety of problems, including a relatively long time to reach equilibrium, volume shifts, Donnan effects, hindering the passage of free ligand, nonspecific adsorption to dialysis apparatus (particularly important for lipophilic drugs and/or proteins), presence of radiochemical impurities and radiochemical instability when a radiolabeled drug is used, protein leakage into the dialyze and difficulty in the control of some experimental variables (e.g. pH of the dialyzate). The major controversy with ultrafiltration involves the stability of the binding equilibrium during the separation process. It is therefore advisable to verify, especially in the case of low-affinity interactions, the basic assumption that the binding ratio of protein bound to free drug remains constant. Ultracentrifugation is an alternative to both ED and ultrafiltration, since it eliminates the problems associated with membrane effects and permits the separation of the free and protein-bound fractions in a “natural environment”, i.e. without addition of buffer systems and, therefore, dilution problems. However, comparative binding studies with different drugs have revealed that there are quantitative discrepancies between results obtained by ED (or ultrafiltration) and by ultracentrifugation. As was pointed out, the error in the estimation of the free drug concentration can be influenced by physical phenomena such as sedimentation, back-diffusion, viscosity and binding to plasma lipoproteins in the supernatant fluid. The possible floating of lipoprotein fractions interfered mainly with

the determination of the binding characteristics of basic drugs.(92)

### 3.2 Chromatographic Methods

There are two most important approaches in chromatographic methods which have been introduced as a powerful tool in drug–protein binding studies:

- affinity (bio)chromatography based on immobilized proteins (or enzymes) in form of a PSP,(94–97)
- HPLC methods operating without chemical (covalent) immobilization of proteins, creating so-called “dynamic equilibria”.

The selection of a particular method is dependent on the binding strength of the drug–protein complex and on the amount and the purity of protein fractions which are injected into the system. Since only relatively few proteins are available in highly purified form and in microgram amounts, this becomes a limiting factor for the wider expansion of so-called conventional HPLC techniques in drug–protein binding screening studies. Major attention has been drawn to miniaturization of the experimental set-up leading to microscale techniques (and this trend has been successfully explored in CE). In addition, in order to establish physiologically relevant correlations (prediction of drug uptake through epithelial cell membrane), immobilized-(proteo)liposome chromatography(95,98,99) and immobilized artificial membrane (IAM) HPLC(96) have been introduced. Focused attention should be drawn to conformational changes of immobilized proteins (also if the pH is adjusted or an organic modifier is introduced), since binding behavior and thus derivation of the binding data/binding model could be affected significantly in this way.

#### 3.2.1 Affinity Biochromatography: Protein Stationary Phase

Proteins (receptor proteins) as immobilized (chiral) selectors in HPLC have been used for bioaffinity screening purposes in order to select active ligands/drugs. This is also the subject of screening for combinatorial purposes in order to select active ligands/drugs. The advantages of this approach are represented particularly by the following points.(94,100,101)

- relative stability and constant binding behavior of immobilized proteins (PSPs);
- precision, reproducibility and time efficiency of the chromatographic system permitting large sets of comparative and screening binding experiments;
- effectiveness of the PSPs achieved by changing the protein conformation through modifications of the mobile phase (pH, presence of organic modifier or “additives” of particular interest, e.g. metal ions such as Ca$^{2+}$, Mg$^{2+}$ or Zn$^{2+}$) and using small amounts of drugs (also in the form of their enantiomers) as well as different competitors in order to study drug–drug or enantiomer–enantiomer interactions;
- ability to perform (enantioselective) studies even if there is a tendency towards instability of drugs (e.g. if the enantiomers undergo racemization in aqueous media).

Apart from some inconsistencies regarding results obtained with human serum albumin (HSA) versus bovine serum albumin (BSA), studies with, for example, 1,4-benzodiazepine derivatives,(101–104) 2-arylpropionic nonsteroidal anti-inflammatory drugs (NSAIDs),(105) coumarin derivatives,(79,100,106) Vinca alkaloids(107) or triazole derivatives(108) have confirmed that HSA/PSP is able to reflect accurately the binding behavior of “non-immobilized” HSA, including its inherent enantioselectivity. Thus, HSA/PSP has been successfully used for the extraction of quantitative binding parameters and a qualitative probe for the evaluation of drug–drug interactions (noncooperative, cooperative and independent binding). In contrast to HSA, immobilized AGP seems not to be a suitable screening tool for molecular mimicking of the binding properties of AGP in solution. This is most probably caused by the immobilization procedure leading to “reorientation” or “cross-linking” of specific protein functional groups (particularly sialic acid residues), which are co-responsible for high-affinity attachment of (cationic) drugs.

Owing to their complexity, many specific points concerning the recognition abilities and operating mechanisms of PSPs remain to be clarified. However, assuming that the immobilization procedure does not influence the binding properties of the protein, this experimental approach may provide useful information on (a) binding affinity (and eventually also on number of binding sites involved) and (b) binding area(s) where the specific interaction takes place. This has been transparently done, e.g. when interspecies differences for drug interaction with albumin have been addressed.(94,97)

#### 3.2.2 High-performance Liquid Chromatography Methods Using "Secondary and Dynamic Equilibria"

Several HPLC modifications of size-exclusion chromatographic techniques for binding interactions have been described and compared based on their efficiency to extract reasonable binding characteristics.(108)
• HD method;¹⁰⁹–¹¹²
• vacancy peak (VP) method;¹¹³
• FA;¹¹⁴–¹²⁰
• zonal elution;¹²¹
• retention analysis.¹²²–¹²⁴

The basic principle and methodological differences between HD, VP and FA methods, as these methods are the most commonly used, are illustrated in Figure 3. HPLC methods operating on the size-exclusion principle were further optimized by introducing the internal surface reversed-phase (ISRP)-type “restricted access” materials,¹²⁵,¹²⁶ combining the principles of size-exclusion and bonded-phase partitioning separations. Applying this approach under equilibrium conditions, (free) drug molecules are able to enter the pores of the ISRP column and partition on the internal surface of pores contrarily to large protein (and protein-associated drug) molecules, eluting in the column interstitial void volume.

3.2.2.1 Hummel and Dreyer Method In the HD method, the column is equilibrated with a mobile phase containing a given concentration of drug in phosphate buffer. When the drug–protein complex is injected, equilibrium between the ligand and protein is rapidly re-established in accordance with the free ligand concentration in the mobile phase. The protein and drug–protein complex elute in the column interstitial void volume and the ligand migrates according to its pore volume penetration and distribution in the stationary phase. For the quantification of bound drug, internal or external calibration procedures have been established and compared.¹⁰⁹,¹¹⁰,¹¹² If a column meets the requirements of nonadsorption but size exclusion of proteins with concurrent chromatographic partitioning of the ligand (e.g. diol or ISRP columns), the bound concentration can be measured directly, while the free ligand concentration is controlled in the mobile phase as the true independent variable. Obviously, this method provides an efficient means of determining accurate binding parameters for protein–ligand equilibria:

- occurring at more than one type of binding site (concomitant presence of high- and low-affinity binding sites);  
- if multidrug–protein interactions are to be taken into account;¹¹¹  
- in the case of highly protein-bound hydrophobic drugs;  
- when binding differences of individual drug enantiomers have to be compared precisely.¹²⁷–¹²⁹

The most relevant disadvantage of this method is related to the restriction to use only purified protein (or biopolymer) samples. It remains to be clarified whether the downsizing of the analytical set-up [e.g. using CEC] could be adopted in case of this method.

3.2.2.2 Vacancy Peak Method (Equilibrium Saturation Method) When both interacting species (ligand and protein) are implemented as eluent constituents, after achieving equilibrium, injection of a small buffer volume results typically in two negative peaks. The first corresponds to the protein–ligand complex and from the second the free drug concentration can be determined.¹¹⁰,¹¹³ Since the solubility of a substance increases in the presence of a protein, this approach is of particular interest for poorly soluble drugs and for studying competitive binding aspects [e.g. influence of FFA or sodium dodecyl sulfate (SDS) on warfarin–HSA binding].¹¹⁰

Overlooking some other limitations (e.g. excessive amounts of material required), the presence of protein in the mobile phase results in high background absorbance and an internal calibration is usually needed.

3.2.2.3 Frontal Analysis In the FA method [high-performance frontal analysis (HPFA), FA], a large volume of drug–protein mixed solution is applied continuously to a size-exclusion column to achieve a steady-state...
concentration. The elution profile obtained consists of α-, β-, and γ-plateau zones corresponding to the free protein, mixture of protein-bound ligand and free ligand, respectively. Earlier applications of this method indicated that large sample volumes are necessary to observe a clear γ-plateau for hydrophilic drugs (e.g. >10 mL for warfarin).\(^{(109,117)}\) Updated analytical set-ups [using, e.g., hydrophilic poly(vinyl alcohol) gels] enabled the sample volume to be decreased dramatically (by a factor of at least 10) and the free drug concentration to be determined also for relatively hydrophilic drugs (e.g. salicylate or acetazolamide) exhibiting weak protein binding.\(^{(130)}\)

The HPFA method is advantageous particularly for the estimation of the concentration of unbound hydrophobic drugs, since

- relatively small sample volumes are injected (100 µL–2 mL, depending on the free drug fraction);
- untreated plasma samples may be injected;
- strong adsorption effects interfering by using conventional separation approaches are eliminated;
- column-switching systems facilitating simple, rapid and (stereo)specific separation could be used.\(^{(120)}\)

On-line coupling of HPFA and chiral HPLC offers the prospect of direct and enantioselective quantification of unbound drug under protein binding equilibrium conditions, as has been shown for enantiomers of warfarin,\(^{(115)}\) ketoprofen,\(^{(116)}\) fenoprofen,\(^{(114)}\) nilvadipine,\(^{(120)}\) xanthine oxidase inhibitor, BOF-4272\(^{(113)}\) and levo-/semotiadil.\(^{(132)}\)

In addition, this methodological approach is suitable for revealing species-dependent or concentration-dependent aspects of stereoselective binding.\(^{(131)}\)

### 3.2.2.4 Other Chromatographic Methods

**Retention Analysis: Protein as Mobile Phase Additive.**

Since the retention volume of a ligand eluted by a protein solution depends on the association of the ligand with the protein, the binding affinity of interaction can be determined using the protein as a mobile phase additive (i.e., protein pseudostationary phase). Differences in retention volumes in the absence and presence of the binding protein could be used to calculate the corresponding binding characteristics (i.e., total affinity, denoted \(m \sum_{i=1}^{m} n_i k_i\)). According to Equation (1),\(^{(122,123)}\)

\[
\frac{V_R' - V_0}{V_R - V_0} = \frac{1}{1 + \sum_{i=1}^{m} n_i k_i P_i}
\]

where \(V_R\) and \(V_R'\) are the retention volume in the absence and presence of the protein, respectively, \(V_0\) is the void volume of the chromatographic column, \(n\) is the number of binding sites, \(k\) is the binding constant of the interaction and \(P_i\) is the total concentration of the biomacromolecule (receptor). Since proteins interact strongly with silica-based solid phases, questions have been addressed about the adsorption of, for example, albumin to different materials comparing hydrophobic (RP-8, phenyl) and hydrophilic (diol) groups; optimal conditions (with only negligible protein adsorption) were achieved on a diol-type support. The introduction of diluted albumin solution (\(<80\mu\text{mol L}^{-1}\)) functioning as a chiral pseudostationary phase resulted in the successful separation of, for example, enantiomers of lipophilic omeprazole\(^{(124)}\) and hydrophilic tryptophan. The main requirement of this methodology is related primarily to the stability of the bound/free drug ratio during analysis and this is solved experimentally using small amounts of drug injected.\(^{(106)}\)

**Zonal (Elution) Chromatography.**

If the binding equilibrium is not disturbed or modified by the interaction of a drug with a buffer-equilibrated stationary phase, samples containing both ligand and protein could be analyzed by direct injection. In principle, the protein–drug complex elutes first and is followed by a second peak corresponding to the free ligand: the validity of binding parameters is dependent on the interaction kinetics, assuming stability (non-dissociation) as one of the components is eluted from the zone. This method is appropriate particularly for high-affinity complexes (with \(K_a > 10^6 – 10^7\text{ L mol}^{-1}\), i.e., values concerning to affinities of hormones to their specific protein transporters). Its application for “middle-range” drug binding affinities (\(K_a = 10^3 – 10^4\text{ L mol}^{-1}\)) is not possible, since their dissociation kinetics are faster than the chromatographic elution process. Along this line, some authors have demonstrated the use of zonal chromatography for clinical therapeutic drug monitoring of free drugs in serum [e.g., free phenytoin with a limit of detection (LOD) of 0.1 µg mL\(^{-1}\) by injecting sample volumes of 250–450 µL\(^{(121)}\)].

### 3.3 Capillary Electrophoresis

In the past decade, various forms and modifications of CE have been rationalized and applied to the characterization of noncovalent ligand–protein binding interactions. Proteins may be used as:

- dynamic protein coating of the capillary (as renewable PSPs);
- soluble additives of running buffers in ACE, VACE;
- cross-linked/immobilized in capillary affinity gel electrophoresis (CAGE);
- immobilized in affinity CEC;
- similarly as in HPLC, the FA, HD or VP method can be adopted.
3.3.1 Affinity Capillary Electrophoresis

The main advantage of ACE over affinity HPLC with dynamic equilibria for the evaluation of biospecific binding interactions resides in the following:\(^{133-137}\):

- miniaturization of the experimental set-up and, therefore, significantly smaller amounts of (non-purified) protein or ligand have to be introduced when "equilibrium conditions" should be established;
- creating of a "pseudophysiological" environment for biospecific drug–protein or protein–protein interactions, eliminating the difficulties related to the use of different (more or less) biocompatible HPLC stationary phases;
- gathering quantitative (or qualitative) information on binding interactions by using a ligand or protein as a buffer (BGE) additive or implementation of both interacting species in the running buffer (VACE), i.e. no protein immobilization is required;
- direct enantioseparation if stereoselective drug binding occurs.

If the protein is used as a buffer or BGE additive and the solution completely fills the separation capillary including both buffer reservoirs (so-called complete-filling technique), by relating the electrophoretic mobility to binding it is possible to determine ligand (L)–protein (P) binding parameters (Equation 2):\(^{138}\)

\[
\mu = \mu_f \frac{[L]}{[L] + [LP]} + \mu_p \frac{[LP]}{[L] + [P]}
\]  

where \(\mu\) is the overall mobility of the analyte, \(\mu_f\) is the mobility of the free analyte, \(\mu_p\) is the mobility of the analyte–protein complex and \([L]\) and \([LP]\) are the concentrations of the free and complexed ligand, respectively. When monovalent binding is considered, by substituting \(K_a = [LP]/[L][P]\), Equation (2) transforms to Equation (3):

\[
\mu = \mu_f + \mu_p K_a [P] \frac{1}{1 + K_a [P]}
\]  

where \(K_a\) is the equilibrium association constant and \([P]\) is the free protein concentration. However, determination of binding affinity by using this approach may become complicated, as can be seen in Table 4, demonstrating that

the measurement of quantitative binding characteristics has been performed rather exceptionally. The main difficulties reside in the accurate determination of $\mu_p$, in a large detector response itself, in the presence of zone-broadening processes or in exact temperature control. Special attention should be paid further to protein–wall adsorption phenomena and an appropriate (reproducible) capillary coating is often necessary. In addition, as has been pointed out, enantioseparation of some drugs achieved using proteins as a buffer additive in CE cannot always easily be reproduced by affinity HPLC (with PSPs) and vice versa. This could be explained most probably by different protein concentrations (and thus available protein binding sites) in each system. In CE, the HSA used as a buffer additive is usually at tens of micromolar concentration, whereas HSA immobilized as a chiral selector in affinity HPLC may approach millimolar levels. As already suggested, the main advantage of this approach is that the injected ligand may be a racemate, and if stereoselective binding occurs, a chiral separation could be achieved. By these means, stereoselective interactions of (±)-ofloxacin with different albumins (either chemically modified or from different biological species) were investigated, and stereoselective species-dependent binding aspects and relevant displacement interactions were described. Further examples and aspects evaluated are listed in Table 4 and the principal working schemes are depicted in Figures 4 and 5.

An alternative approach is to use the so-called partial-filling technique, i.e. conditions in which the protein solution fills only part of the capillary (starting from the injection end of the capillary). Since the protein is not present at the detector window, this approach can achieve better sensitivity than complete-filling ACE methods. This could be further optimized by coupling of ACE with mass spectrometry (MS), as demonstrated by Terabe et al.

When the ligand is used as buffer additive, derivation of the respective binding parameters is straightforward also considering numerous interfering factors as described above, and this alternative has been proved successfully in several binding studies (Table 5). A “historic” form of ACE for drug–protein studies is represented by the conventional affinity electrophoresis in agarose gels [agarose gel electrophoresis (AGE)]. The experimental set-up of AGE was updated recently with heterogeneous (multi)sectioned slab gels, improving the run efficiency. Dissociation constants in the nanomolar range could be determined in this way, but if only minor migration shifts occur the estimation of binding characteristics is not possible for practical reasons. In principle, if the protein binds a (charged) ligand of relatively small mass, the change in

---

**Figure 4** Schematic illustration of (a) sample injection and (b) electrophoretic separation of protein-bound and free drug using immobilized (or adsorbed) protein in CE. In this format, the applied electric field creates a flow of solvent and solute (drug) through the system. Direct enantioseparation of chiral drugs suggesting enantioselective binding differences could also be detected in this way.

**Figure 5** Schematic illustration of (a) sample injection and (b) electrophoretic separation of protein-bound and free drug using nonimmobilized protein (e.g. protein as buffer additive) in CE. The CE system contains a fixed concentration of protein in the running buffer and if solutes (drugs) are recognized via more or less specific binding interaction(s), a change in their mobility could be detected. Enantioselective binding could be resolved based on the corresponding shifts in drug mobilities.
its electrophoretic mobility (µ) due to the change in mass [from $M^{2/3}$ to $(M + m)^{2/3}$] is small relative to the change in µ due to the change in charge (from Z to $Z + z$). Therefore, the protein–ligand complex migrates at a different rate to the uncomplexed protein: by measuring migration times as a function of the concentration of a (charged) ligand present in the buffer, it is possible to use Scatchard analysis to estimate the affinity constant, $K_b$ (Equation 4):

$$\frac{\delta \Delta t}{\delta \Delta t_{\text{max}} [L]} = K_b - K_b \frac{\delta \Delta t}{\delta \Delta t_{\text{max}}}$$

(4)

where $\delta \Delta t$ is the difference between the migration time of the protein of interest and the reference protein ($\Delta t = t_{\text{red}} - t_{\text{interest sample}}$) at concentration [L] of the charged ligand, $\delta \Delta t = \Delta t - \Delta t_0$ ($\Delta t_0$ is the value of $\Delta t$ at [L] = 0), and $\Delta t_{\text{max}}$ is the value of $\Delta t$ at saturating concentrations of L. (The reference protein is usually another protein having a similar value of migration time but which does not bind the ligand studied.) If the migration time is affected by changes in electroosmotic flow (EOF), Equation (4) is not accurate for estimating binding affinity and has to be corrected accordingly. Direct analysis of the interaction of protein with electrically neutral, low-molecular-weight ligands using this approach does not seem possible, since the neutral ligand does not introduce a sufficient change in charge (or charge distribution) of the protein–ligand complex. Hence the mobilities of uncomplexed and complexed protein cannot be distinguished from each other. An alternative estimation of the binding constant is possible when, for example, a neutral ligand competes with a charged ligand of known binding constant.\(^{156}\) The validity of Equation (4) is restricted to monovalent binding. Nevertheless, an optimized experimental protocol has been suggested also for the determination of bi- and multivalent binding stoichiometries.\(^{40}\)

A typical design of ACE experiments for deducing quantitative binding characteristics requires multiple experimental runs at different concentrations of the ligand; the use of a multiple-plug binding assay has been attempted recently in order to avoid this practical limitation.\(^{159}\)

For specific purposes, labeling of one molecular species [affinity probe CE] using a fluorophore [followed by laser-induced fluorescence (LIF) detection]\(^{154}\) could expand the applicability of ACE for the evaluation of drug (ligand)-binding equilibria. Fluorophore-labeled molecules can be detected at very low concentration ($\sim 10^{-9}$ mol L$^{-1}$), which is particularly important in the case of high-affinity complexes (dissociation constant in the nanomolar range). When the ligand of interest is not charged or the number of the charges is not sufficient to induce the required mobility change of the binding protein, it could be modified with an affinophore. Affinity constants of divergent lectins for neutral sugars have been derived in this way on the microscale.\(^{155}\)
The major problem of CE methodology remains the tendency of proteins to adsorb on the wall of uncoated capillaries. This particular problem is most commonly minimized either by coating the capillary wall or by adjusting the pH of the electrophoresis buffer. (134)

3.3.2 Vacancy Affinity Capillary Electrophoresis

In the VACE method, both interacting species are added to the buffer, whereby the concentration of one is fixed and the concentration of the other is varied (most commonly, the protein concentration is kept constant).

Similarly as in the VP method in HPLC, the injection of a small volume of buffer leads to the occurrence of two negative peaks. The area of the first peak corresponds to the concentration of free protein and the second peak reflects the concentration of the complex and free drug in the buffer. Unlike the calculation of peak areas, information on the association constant can be obtained from their migration shifts. There are two principal possibilities for the extraction of binding parameters when using VACE in binding assays, the shift in the mobility of the drug (µ_{D,P}) and the shift in the mobility of protein (µ_{P,D}), and both can be plotted against the “total” drug concentration in the buffer. As stressed by Busch, (168) the main advantage of the VACE method is that the plot of µ_{D,P} vs total drug contains information on the absolute number of different binding sites present on the protein.

In the other case (and similarly as in ACE), i.e. plotting µ_{P,D} versus drug concentration in the buffer, it is possible to obtain the affinity constant value, but not the absolute number of binding sites. As with the VP method in HPLC, the VACE method is well suited for hydrophobic ligands, even in cases of multiple equilibria.

3.3.3 Hummel and Dreyer and Frontal Analysis Method Adapted to Capillary Electrophoresis Conditions

Similarly as in HPLC, FA and HD methods have been adapted to CE conditions. (128, 168-170) Using FA [high-performance capillary electrophoresis/frontal analysis (HPCE/FA)], both nonstereoselective (119) and stereo-selective (171) aspects of drug–protein interactions have been described. Compared with HPLC/FA, the sample volume in HPCE/FA is small (~80–200 nL) and since the separation is based on the measurement of differences in electrophoretic mobility of interacting components, interactions between molecules of similar size (but different electrophoretic mobility) should also be considered. HPCE/FA with electrokinetic injection could be adopted only when the drug and the protein migrate in directions opposite to each other, hence it is readily applicable particularly for positively charged drugs. (171) In turn, HPCE/FA following hydrodynamic injection is much more robust and is applicable for basic, acidic and neutral drugs (as long as electrophoretic mobility differences exist between drug and protein). The use of HPCE/FA has been proved useful also for the determination of binding parameters of a hapten (drug)–antibody complex (with dissociation constants in the nanomolar range): the hapten concentration can be measured directly, enabling one to check also the stoichiometry of the binding model. (170)

The major disadvantage of HPCE/FA is related to the relatively high detection limit and, thus, insufficient sensitivity for the analysis of clinical samples. This holds true also for the HD method which is also more laborious, since a simplified experimental design (111) does not provide satisfactory smooth binding isotherms in CE. (128, 169)

In contrast to FA, the HD method could not be coupled with chiral separation, since detection is indirect. Its use could be recommended, e.g. for monitoring the binding parameters of highly lipophilic drugs [e.g. for carvedilol enantiomers the analysis time could be effectively reduced, i.e. from ca. 40 min in HPLC to ca. 15 min in CE (129)].

Summarizing, if both interacting species are detectable and their mobilities are different, both ACE and VACE can be considered as complementary techniques. Specifically, with the VACE method it is possible not only to derive the association constant(s), but also to characterize the number of binding sites (this is particularly important when multivalent binding models are considered). Thereby, a very significant contribution to minimizing systematic errors involved in VACE or ACE method could be obtained by decreasing the concentration of one of the interacting species to as low a level as possible. (168)

Assuming that the mobility of the protein is equal to the mobility of the drug–protein complex, as an alternative, both FA and HD methods can be used for deriving quantitative binding parameters. Since the HD method always requires a certain calibration procedure (internally or externally), FA could be seen as methodologically advantageous in terms of its experimental versatility (including material and handling requirements) and ability to derive complete sets of reliable binding characteristics. (119, 168, 171)

3.3.4 Capillary Electrochromatography

CEC is a hybrid technique of HPLC and CE attempting to eliminate their individual disadvantages (e.g. large-scale set-up of HPLC consuming large amounts of samples, mobile phases, mobile phase additives and packing materials) and exploring certain advantages (e.g. the use of neutral species as compared with CE, leading to unique selectivity). (98) The main operating difficulties are often related to bubble formation within the column (leading to the breakdown of current and EOF) and...
local overheating phenomena resulting in drying out of the capillary. Although not experimentally proved and confirmed yet, CEC could be of interest if miniaturization and/or enhanced separation selectivity for separation of interacting species is addressed. Nonspecific adsorption phenomena of proteins to silica-based surfaces may alter the zeta-potential and thus the EOF resulting in retention time shifts and low reproducibility.

3.4 Affinity Information on Biospecific Interaction with Respect to Immobilization of Interacting Species

Immunoassays such as an enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay (RIA) employing covalent immobilization of one of the interacting species (either an antibody or an antigen) on a solid support or matrix (microtiter plate, glass-fiber surface, etc.) are frequently used to characterize binding models, including the extraction of binding parameters. Beyond some technical difficulties (development of a rational and reproducible immobilization procedure, lot-to-lot variation in solid-phase materials, nonspecific binding of the reactant to a solid matrix, many rinsing steps to wash out unreacted receptor molecules), the reaction kinetics using solid-phase assays are often very slow, requiring several hours (overnight) of incubation. Although the “solid-phase” techniques are experimentally relatively convenient, measurement of reliable binding parameters by this approach seems not to be a straightforward process. Several factors (e.g., antibody valency, steric hindrance, antigen density and mobility on the surface) may severely affect the equilibrium in this heterogeneous phase system. This implies further difficulties in the quantification of “real” affinity constants. As a consequence, only an “apparent” affinity constant (differing from the thermodynamically defined affinity in solution) could be obtained using, for example, ELISA methodology. Ultimately, this has to be taken into account by comparing data sets generated with heterogenous methodologies.

An inventive approach is represented by the development of receptor-based LC stationary phases, e.g., if solubilized nicotinic acetylcholine receptor (nAchR) subtypes are immobilized in the phospholipid monolayer of an IAM. It has been shown that (a) immobilized nAchR preserved its biorecognizing properties after solubilization and immobilization procedure and (b) the affinities of model agonists [epibatidine, (−)-nicotine, carbachol or atropine] were well correlated with the reference method. Hence the method could be employed for the rapid on-line screening of combinatorial pools of potential drug candidates (as in this case of nicotinic-like activity).

Biomolecular interaction analysis (BIA) has been introduced to monitor the kinetics of molecular binding complexation in real time and without the use of labels. In this method, one interactant is immobilized on the sensory chip and the other is injected across its surface using a sophisticated microfluidics system providing a continuous, precisely controlled flow of analyte to the surface of the sensor chip. BIA is based on the principle that two or more molecules interacting in solution induce a change in the refractive index detectable by surface plasmon resonance (at the surface of a sensor chip). Compared with conventional solid-phase methodologies (ELISA, RIA, etc.), one of the most attractive experimental advantages of BIA technique resides in the use of biosamples without prior purification or solubilization. In some cases, changed binding characteristics have been reported owing to its insufficient regeneration capabilities of the chip and another limitation is that a measurable signal requires analytes to be at least of $M_r = 2000–10000$. Comparison of immuno-CE with BIA technology for the characterization of a monoclonal antibody against DNA confirmed good agreement of the binding characteristics derived. However, gradual loss of DNA from the chip during regeneration procedures was noted with BIA as compared with CE, where neither the ligand nor the analyte is reused.

It has been demonstrated that “solution-phase assays” such as ACE can be used for checking of stoichiometric model and estimation of affinity constants regardless of cooperativity. Binding assays taking place in solution eliminate some of the problems associated with solid-phase matrices, since interacting molecules are free from attachment (i.e., without steric hindrance effects), improving the kinetics of binding and the binding equilibrium significantly. Recently, it has been shown that for the quantification of antibody–antigen interactions, statistically reliable binding parameters can be obtained with FA in CE conditions. However, except for a larger sample volume required for a particular binding isotherm (500 μL in CE vs 10 μL with ELISA), the major limitation of CE measurement is related to the poor ultraviolet (UV) sensitivity, so that is not possible to describe quantitatively a high-affinity complex (e.g., antigen–antibodies). If a sophisticated design of the optical path length (capillaries with a bubble-cell or Z- or U-shaped cell) does not lead to a sufficient improvement, another detection method [laser-induced fluorescence immunodetection (LIFID)] could be employed (if available) as an alternative. However, either native fluorescence of the ligand or a specific labeling technology is required to use LIF. High-intensity laser systems are several orders of magnitude more sensitive than UV absorbance (LOD ca. $2 \times 10^{-10} – 2 \times 10^{-9} \text{ mol L}^{-1}$) providing also greater specificity.
be solved in CE by introducing so-called multicapillary arrays.

3.5 Spectroscopic Methods

Compared with separation methods, spectroscopic methods facilitate predominantly an insight into three-dimensional protein structure, elucidating complementary structural and/or conformational variations of a protein molecule resulting from drug attachment. Of the different spectroscopic methods [UV, visible, fluorescence, nuclear magnetic resonance (NMR)] and circular dichroism (CD), fluorescence spectroscopy has been used most widely.\(^{(43,81,176–178)}\) Derivation of quantitative binding parameters is based on measurements of the changes in the intrinsic molar fluorescence (\(F_b\)) of the protein-bound drug (fluorescence quenching). It is a common practice to measure fluorescence at a constant drug concentration and gradually increasing protein concentration, whereby extrapolation of these two parameters enables one to calculate the value of the intrinsic molar fluorescence (\(F_b\)) of the protein-bound drug (fluorescence quenching). It is a common practice to measure fluorescence at a constant drug concentration and gradually increasing protein concentration, whereby extrapolation of these two parameters allows one to calculate the value of the intrinsic molar fluorescence (\(F_b\)) of the protein-bound drug (fluorescence quenching). It is a common practice to measure fluorescence at a constant drug concentration and gradually increasing protein concentration, whereby extrapolation of these two parameters allows one to calculate the value of the intrinsic molar fluorescence (\(F_b\)) of the protein-bound drug (fluorescence quenching).

Of other spectroscopic methods which have been used to characterize drug–protein interactions, proton (\(^1\)H) NMR spectroscopy should be mentioned. However, in order to obtain reproducible and reliable spectra of subtle alterations in protein structure after ligand complexation, high-field NMR spectrometers with advanced resolution and data acquisition and processing technology are required. The interpretation of results is based on the fact that drugs interacting with protein in a nonspecific (i.e., low-affinity) manner show different spectra, often with only somewhat broadened but not resolved signals of drug molecules. In contrast, the more specifically bound drugs usually cause a definite structural change of the “surrounding” protein molecule (and/or the structural changes facilitate the high-affinity binding) and, consequently, in NMR difference spectra the drug signals are either very broadened, shifted or cannot be determined at the positions where the free drug signals were observed.\(^{(179,180)}\) For special purposes, (\(^{19}\)F)-NMR spectroscopy has been successfully used to monitor the interactions of fluorinated drugs (5-fluorotryptophan, 5-fluorosalicylic acid, flurbiprofen and sulindac) with HSA.\(^{(181)}\) Drug-dependent changes in the NMR heteronuclear (\(^1\)H–\(^{13}\)C) spectra have been used for monitoring of drug (bepridil, trifluoperazine) binding sites on cardiac troponin C.\(^{(182)}\)

It is of importance that the signals derived by NMR spectroscopy not only indicate the location of the respective binding site, but also provide information on the residues of protein involved in the drug binding. Current developments in high-field (500–600 MHz) NMR technology offer, owing to the very high resolution of NMR signals, many promising opportunities for detailed mapping of binding interactions including the stoichiometry, kinetics and conformational properties of drug–protein complexes.\(^{(183–185)}\) One- and two-dimensional homonuclear (e.g. \(^1\)H, \(^{13}\)N) or heteronuclear high-field NMR spectroscopy are suitable for the investigation of equilibrium conformational states in order to determine the most favorable structures of the intercalated complexes of different stoichiometries.\(^{(185)}\) Predominantly, however, the mapping of primary (high-affinity) binding sites is usually achieved by using NMR spectroscopy. Monitoring of the additional presence of secondary low-affinity binding sites does not seem possible\(^{(179)}\) and/or has not been described yet. A further limitation of this method is the use of drug concentrations that are not pharmacologically relevant (typically in the millimolar range).

Chiroptical methods, optical rotary dispersion (ORD) or CD, have been proposed as a useful tool to describe dynamic movements of protein conformation (and the role of relevant protein functionalities) in order to obtain more complex information on the binding mechanisms involved.\(^{(186–188)}\) The conformational status of a protein and modification of its secondary and tertiary structure due to complexation with a particular drug are of crucial importance for the binding properties of the relevant binding sites. This has been demonstrated for protein-linked conformation changes of albumin in the physiological pH range 7.0–9.0, with the N-form occurring below neutral pH and the B-form at higher pH (the N–B transition).\(^{(189–192)}\) Consequently, in nonstereoselective assays it has been shown that ligands are bound differently to the N- and B-forms of HSA: warfarin and diazepam exhibited higher affinity for the B-form,\(^{(193,194)}\) suprofen and benoxaprofen were bound preferentially to the N-form,\(^{(195)}\) whereas suprofen affinity did not seem to be affected by the N–B transition.\(^{(196)}\)

Evaluation of possible conformational alterations of acceptor molecules are of major significance for the description of the binding mechanism of stereoselective interactions and should be considered in the experimental study design.

In comparisons of binding studies evaluating both qualitative and quantitative aspects of drug–protein interactions by employing a variety of complementary techniques (ED, UV, fluorescence, CD and NMR), a clear discrepancy between results acquired from CD vs ED has been observed as related to the binding mechanism. Monitoring of heterogeneous binding processes (concomitant presence of low-affinity binding
components) is usually not possible by CD, hence quantitative information derived from such studies should be interpreted carefully.

3.6 Other Methods and Future Trends in Analytical Methodology

Some other methods have occasionally been used in the framework of drug–protein binding studies, with respect to unique features of the ligand or to reveal specific quantitative or qualitative aspects of binding interaction. Examples include the use of

- polarography \(^{(113,197)}\)
- (micro)calorimetry \(^{(198,199)}\)
- stopped-flow experiments [this approach was able to elucidate, for example, different albumin binding kinetics in diabetics \(^{(200)}\);]
- fluorescence polarization immunoassay (FPIA), introduced mainly for routine therapeutic monitoring of free levels of drugs with a narrow therapeutic index.

Apart from “main-stream” analytical (separation) techniques, interesting potential resides also in other methods, such as field flow fractionation (FFF), permitting also analyses of raw and complex biological samples (protein mixtures, aggregates, cells, etc.). \(^{(201,202)}\)

4 IN VIVO MONITORING OF FREE FRACTION OF DRUGS: MICRODIALYSIS

The sampling and determination of the “true” free drug fraction in vivo, i.e. in a dynamically stirred biological system with many interlocked processes, is of primary pharmacological importance. Obviously, a complex methodological approach should reflect the existing organ-specific differences as well as “free intermediate action”, i.e. the fact that part of the initially bound drug is eventually released, depending on the capillary transit time, the rate of dissociation of the drug–protein complex and the permeability and surface area of the capillaries. \(^{(203–205)}\) Although measurements of saliva or cerebrospinal fluid have been proved to estimate the free drug fraction, they are of only limited general utility for free drug therapeutic monitoring. \(^{(206,207)}\) The use of the microdialysis perfusion technique was proposed as an in vivo alternative for the study of the steady-state free fraction of drugs in different tissues and body compartments. \(^{(208)}\) In microdialysis sampling, a hydrophilic capillary (small-diameter dialysis tubing) is implanted in compartment(s)/tissue(s) of particular interest. By perfusion of the capillary with a perfusate solution at a low flow rate (usually less than 1–2 µL min\(^{-1}\)), low-molecular-weight compounds diffuse into the perfusate, in contrast to proteins (and other higher-molecular-weight compounds), which do not enter the perfusion medium. In summary, microdialysis offers advantages in terms of maintaining equilibria and experimental versatility in vivo (time-dependent sampling, rapid continuous sampling avoiding enzymatic degradation of the sample, or sampling in awake, freely moving animals). The alternative use of this method for in vitro plasma protein-binding studies has been verified in modified experimental set-ups for determination of the free concentration of drugs (paracetamol, procainamide, caffeine, theophylline, lidocaine, carbamazepine, phenobarbital and phenytoin) in vitro. \(^{(209)}\) The results obtained confirmed that microdialysis is capable of operating effectively by preserving binding equilibria over a wide range of drug concentrations and protein binding. Since it is possible in animal experiments to implant the microdialysis probe(s) intravenously, the extent of drug binding to proteins could be studied temporarily in vivo. Owing to the relatively small volumes of samples acquired (a few microliters depending on the collection rate, which is usually 0.1–5 µL L\(^{-1}\), and typical sampling intervals are 1–5 min), the major limitation of microdialysis could be related to the poor sensitivity of most of the currently available HPLC (or CE) systems. Capillary ultrafiltration, employing an active-pressure gradient instead of a passive diffusion concentration gradient for the sampling process, is another new technique with the ability to monitor unbound drug in biological systems in vivo. \(^{(210)}\)

5 EVALUATION OF BINDING DATA

In principle, there are two possibilities for the interpretation of reversible ligand (L)–protein (P) interactions, i.e. “real binding site” (Equation 5) and “stoichiometric” (Equation 6) concepts. \(^{(211)}\)

\[
B = \frac{k_1 L}{1 + k_1 L} + \frac{k_2 L}{1 + k_2 L} + \ldots + \frac{k_n L}{1 + k_n L} \quad (5)
\]

\[
B = \frac{K_1(L) + 2K_1K_2(L)^2 + \ldots + n(K_1K_2\ldots K_n)(L)^n}{1 + K_1(L) + K_1K_2(L)^2 + \ldots + (K_1K_2\ldots K_n)(L)^n} \quad (6)
\]

The binding constants (i.e. \(k_1, k_2, k_n\) vs \(K_1, K_2, K_n\)) derived by the two approaches are not the same either in magnitude or in the binding step to which they have to be assigned. \(^{(42,212)}\) Stoichiometric formulation using Adair’s binding equation (Equation 6) neglects the rather conventional concept of rigid and independent
binding sites attached by a particular ligand. It can be applied for any multiple binding mechanism, irrespective of whether the ligand molecules are bound cooperatively, independently or anticooperatively. Moreover, in this model, the sequential binding of ligands is reflected by the conformational adaptability of protein binding sites and it could explain more transparently its ability to bind two or more ligand molecules to one binding locus. From a theoretical point of view, the stoichiometric model provides the most versatile format and it could be reduced by additional conditions to the “site” (Scatchard) model. In practice, Adair’s equation is not as popular as Scatchard’s; however, it offers a more complete view of so-called “nonreceptor” (e.g. albumin) drug-binding interactions.\(^{213,214}\)

The usual approach in ligand binding studies is to fit the experimental data to Equation (5) and to plot them in the form of a so-called Scatchard plot\(^{215}\) (Figure 6a–c). The most important limitations concerning this approach include either the oversimplification of ligand attachment to the binding site(s) by fitting of curvilinear plots with straight lines or, contrarily, the detection of visually, biochemically or pharmacologically not interpretable acceptor heterogeneity.\(^{216–220}\) At least in part, a number of experimental artifacts depending on the methodology applied may explain the curvilinear nature of Scatchard plots. The reasons for downward curvature are represented predominantly by incomplete recovery of the bound fraction, irreversible ligand binding or its internalization, ligand or acceptor degradation and nonequilibrium binding conditions. Upward curvature is usually caused by an affinity difference between labeled and unlabeled ligands, imprecise estimation of nonspecific binding or by contamination of the bound fraction with unbound ligand.\(^{220}\) Some factors (impurities in labeled ligand preparation or influence of membrane microenvironment) may result in either upward or downward curvature of Scatchard plots. On the other hand, by choosing an inappropriate analytical method for measuring binding data sets, some low-affinity binding components may be overlooked (Figure 6a–c). In addition, another obvious reason for variability of binding parameters is that a ligand’s association constant and/or the number of binding sites increases when the acceptor (receptor or protein) preparation is diluted.\(^{216}\) This point is related partly to the very common situation when a competitive inhibitor (or contaminant) of binding is present in the acceptor preparation. Obviously, all the above-mentioned aspects are plausible also for the evaluation of stereospecific drug–protein interactions (including enantiomeric contamination).

Generally, although Scatchard plots will probably be used further for illustration and comparison of different binding data sets, for quantitative evaluation purposes some alternative graphical representations must be considered. The major advantage of these\(^{217,218}\)
is the direct representation of experimental data. As pointed out, the application of linear regression to transformed (Scatchard) data in order to calculate the binding parameters could no longer be accepted as an appropriate quantitative approach.

6 CONCLUSION

Description of interactions of proteins (and also peptides, enzymes, DNA, antigens, fragments of membranes or cells, etc.) with ligands (drugs and other xenobiotics, endogens, ions, metals, etc.) is an issue of vital importance in bioscience. Although some exceptions for specific purposes may exist, an “optimal methodology” for characterizing the principal functional criteria of binding interactions (i.e. bioaffinity, selectivity, specificity, stoichiometry, saturability and stereoselectivity) should exhibit

- methodological (bioanalytical) power (e.g. sensitivity, speed, precision, validity, versatility, cost effectiveness);
- broad applicability (microscale set-up for, for example, rarely available interacting species, use of crude or complex samples of biological origin);
- ability to reflect (or mimic) the structural or functional complexity of biological systems [creating pseudophysiological experimental equilibria for measuring and derivation of binding characteristics, including implementation of (proteo)liposomes, artificial membranes, etc., and also optional extrapolation of binding results from in vitro conditions to an in vivo situation];
- screening abilities for direct and rapid screening of combinatorial libraries of drug candidates.

Unlike conventional (e.g. ED, ultrafiltration) or alternative analytical methods suffering from intrinsic methodological restrictions (e.g. spectroscopy, NMR), particularly (affinity) HPLC and CE are of general applicability for monitoring of biospecific intermolecular interactions. The practical utility of conventional affinity HPLC is somewhat limited, since relatively large (milligram) amounts of purified protein/biopolymer are needed [applicability almost exclusively to binding studies with albumins]. Of other HPLC methods for screening of binding affinity, HPLC/FA is undoubtedly the most robust alternative, especially with regard to the complexity of the biological matrix applied and the possibility of coupling FA with a stereoselective assay via different column-switching devices.

On the other hand, it seems likely that different variants of (affinity) CE may play a pivotal role in future methodological developments, since

- they exhibit great experimental versatility for large sample sets;
- several orders of magnitude smaller amounts (volumes) of ligands and purified but also nonpurified biosamples (membranes, liposomes, biomolecular “aggregates”, vesicles, cells) are required compared with HPLC;
- binding studies can be performed in “free solution”, nondenaturing “pseudophysiological” buffered aqueous media, hence a broad variety of drug–protein, but also ligand (drug)–DNA, protein–protein, (drug)–vesicles–protein and (drug)–cell–cell interactions may be studied by this methodology.

As drugs or proteins may be implemented as buffer additives and immobilization of interacting species in CE is only optional (if needed for specific purposes), derivation of binding characteristics and the re-establishment of “starting” conditions for repetitive analyses are relatively uncomplicated. The dynamically growing number of applications of ACE underlines further that the CE approach offers effective and convenient toolkits, even if only minute amounts of biopolymer are available or if multiple equilibria, nonspecific (weak) or stereoselective binding interactions are considered. Further technical improvements (e.g. laser detection systems, multicapillary arrays) and their practical availability will probably broaden further the use of CE for both “nonroutine” and “routine” applications.

The most challenging future prospects are represented by the on-line coupling of microscale bioanalytical methods with desired combinatorial potential (e.g. microdialysis and tandem CE coupled with MS) bridging, for example, the “in vivo approach” with highly advanced analytical tools. Most recently, CE has been carried out in microchannels (made by photolithographic etching) in a planar chip of glass or fused silica. The advantages of such CE-based competitive immunoassays (using fluorescence-labeled haptenic antigens and LIF) include, in addition to the integrally anchored experimental flexibility, the small amount of sample required (less than 1 amol), short separation times (from 30 s to 1 min), ability to determine multiple analytes simultaneously (drug-screening devices for combinatorial ligand libraries), high sensitivity (LOD of 0.1 nmol L\(^{-1}\)) and accuracy of the instrumentation. Broadening the field of applicability of these or similar techniques in the future may be forecast and this will certainly impact on further achievements in elucidating the biorecognition properties of different biomolecular species, systems and processes.

PROTEIN–DRUG INTERACTIONS

The specific binding of a protein to a nucleic acid is a first step in several central processes in a living cell. Sequence-specific protein–DNA interactions are crucial for the functional read-out of genetic information. Sequence recognition is the result of a concerted action of many weak chemical interactions of different types between the protein and its DNA target, including nonspecific electrostatic interactions, hydrogen bonding and van der Waals contacts. The precise complementarity of shape between the two macromolecules facilitates specific chemical recognition to be established. The electrophoretic mobility shift assay (EMSA) and several variants of footprinting are simple electrophoretic methods developed to study protein–DNA interactions. Because the specificity is determined by the nucleic acid sequence, the same methods can be exploited for a wide range of proteins simply by changing the sequence of the nucleic acid. EMSA detects sequence-specific DNA-binding activity in a protein sample as a separate migrating band in a nondenaturating gel. A footprinting method provides more detailed information on the precise location of a bound protein along the DNA fragment through the removal of specific bands in a pattern of cleaved fragments separated by electrophoresis. Both methods are highly sensitive due to the use of radioactively labeled oligonucleotides and can be performed with protein samples of low purity. When combined these methods are capable of providing a picture of the protein–DNA complex with a great deal of molecular detail, surpassed only by the more demanding methods of crystallography and nuclear magnetic resonance (NMR).

1 PRINCIPLES OF PROTEIN–OLIGONUCLEOTIDE INTERACTIONS

Nucleic acids function in living cell as molecules that store and transport information. The genetic information encoded in the nucleotide sequences can only be converted into functional processes after interaction with specific proteins that are able to recognize and “read” the sequence information. Hence, the specific binding of a protein to a nucleic acid is a first step in several processes where sequence information is controlling cellular functions, like transcription, splicing and DNA repair. Protein–DNA and protein–RNA interactions are therefore instrumental for the functional read-out of genetic information. Although the subjects of research in this area are quite complex and diverse, the basic methods used to study such interactions are rather simple and uniform. This is largely due to the development of uncomplicated and sensitive methods, like EMSA and several variants of footprinting methods. In these procedures, the specificity is determined by the nucleic acid sequences. Hence, the same methods can be exploited for a wide range of proteins simply by changing the sequence of the nucleic acid. The easy access to synthetic oligonucleotides has further facilitated the study of protein–nucleic acid interactions. Finally, several highly developed systems for expression of recombinant proteins and protein domains encoded by cloned genes have given easy access to the many low-abundance proteins involved in reading genetic information.

1.1 Protein–DNA Interactions

The ability of a protein to recognize and bind preferentially to a specific DNA sequence element in the genome is the result of a concerted action of many weak interactions of different types. The principles governing protein–DNA recognition can be described at two levels, as shape recognition describing the structures in protein and DNA that form complementary surfaces that are able to interact, and as chemical recognition describing the nature and arrangement of chemical bonds involved in nucleotide–amino acid contacts. The precise complementarity of shape between the two macromolecules facilitates specific chemical recognition to be established. The chemical rules can be generalized for any DNA-binding motif, while the stereochemical rules are specific to a particular DNA-binding motif.(1) A brief summary
of some major points is given below. For a more detailed discussion of this topic, several reviews are available.\(^{(1–12)}\)

1.1.1 Nonspecific Electrostatic Interactions

Even if a DNA-binding protein can distinguish a few specific recognition sites in the genome from the vast amount of nonspecific sites, it will also bind DNA nonspecifically. It is important also, from a methodological point of view, to realize that all proteins with a sequence-specific binding property also have a significant affinity for DNA in general independent of sequence. This is because electrostatic interactions with the negatively charged phosphates in DNA make a major contribution to the binding affinity for most of these proteins. It is evident that phosphate interaction will be essentially sequence-independent, and therefore cannot account for specificity. In vivo, the high concentration of nonspecific sites cause these proteins to be DNA-bound all the time, irrespective of sequence, at physiological conditions of pH and ionic strength.\(^{(13)}\) The ratio of specific versus nonspecific binding constants will often be in the range \(10^4–10^6\). The electrostatic contribution to the protein–DNA interaction is also the reason why complexes are highly sensitive to the concentrations of mono- and divalent cations. In the absence of proteins the negatively charged phosphodiester chains in DNA will be partially neutralized by counterions with positive charge. In a normal NaCl solution, it has been estimated that about 70% of the negative charges in DNA will be neutralized at any time by Na\(^+\) ions.\(^{(10)}\) When a protein binds, the counterions in the binding site will be displaced and liberated to the solution, a process that is associated with an increase in entropy. The liberated counterions will have to be incorporated in the true equilibrium constant for the binding process, with the consequence that the apparent binding constant becomes an exponential function of the cation concentration. The affinity of a protein for its DNA target will therefore drop rapidly with increasing salt concentration. For any specific protein it is not only the number of positive charges that determines its nonspecific affinity for DNA. Affinity will also be determined by the precise geometric location of the charged groups in the protein relative to DNA and to which degree a complementary surface of charge optimized for interaction is generated. In addition, the electrostatic interaction also has a role in orienting the protein for a second docking step where more precise hydrogen bond interactions can be established.\(^{(14)}\)

1.1.2 Hydrogen Bonding as Basis for Sequence Recognition

A specific DNA-binding protein has to distinguish its particular recognition sequence in DNA without strand separation. This is possible because each specific base pair exposes a unique pattern of hydrogen bond donors and acceptors in the major groove. Hydrogen bonds can only be formed between closely positioned chemical groups, and therefore the geometry of the interacting protein and DNA structures becomes critical. In B-form DNA the major groove is just wide enough to fit an α-helix. Accordingly, many DNA-binding proteins use an α-helix protruding from the surface of the protein as “recognition helix”.\(^{(4–6,12)}\) Although β-sheet DNA-binding motifs also occur.\(^{(15)}\) The geometry of an α-helix docked in the major groove allows hydrogen bond formations between side chains protruding from the α-helix and the edges of the base pairs. When these two structures fit, a complementary pattern of hydrogen bonds and van der Waals interactions lead to specific binding. When the protein is in contact with a nonsite, complementarity is not established. Since the side chains in the recognition helix of a protein will form hydrogen bonds with water in the unbound state, the number of hydrogen bonds are not necessarily altered upon specific complex formation. However, this number is probably reduced when the protein docks on to a nonsite, making nonspecific binding unfavorable. A closer inspection of the structures involved led early on to the conclusion that two hydrogen bonds are required for each base to be uniquely recognized by a protein (bidentate contact\(^{(16)}\)). Sufficient hydrogen bonding possibilities exist in the major groove for each base pair to expose a unique pattern (ternary code), while the minor groove only allows distinction between AT/TA versus GC/CG base pairs (binary code). The determinations of three-dimensional (3D) structures for many DNA-bound proteins have confirmed the importance of hydrogen bonds in sequence recognition. However, they have underscored the importance of an intricate complementary network of interactions where also water can mediate protein–DNA contacts and thus contribute to the recognition process.\(^{(14)}\)

The minor groove in B-form DNA is deep and narrow and thus less accessible for protein contact. However, several examples are described where the long side chain of arginine extends into the minor groove. The groove width will vary with the sequence being narrower in AT-rich DNA than in GC-rich DNA. In A-form DNA (or in duplex RNA segments) the groove geometries are nearly the opposite of B-form DNA, the minor groove being shallow and wide and the major groove deep and narrow. Accordingly, proteins that bind A-form DNA (like many RNA-binding proteins) often interact with the minor groove. It should be noted that the detailed structure of any stretch of DNA will deviate to some extent (groove width, helical periodicity, orientation of bases etc.) from the canonical A- and B-forms and this form is determined by the sequence of base pairs. A specific shape induced
in DNA by a particular sequence can be an important aspect recognized by a DNA-binding protein.\(^4\)

The lesson drawn from the study of many 3D structures of protein–DNA complexes is that it seems impossible to construct a recognition code predicting which amino acid residue will make close contact with which particular base pair.\(^1\) Within specific families of transcription factors some success along these lines has been obtained.\(^2,6\) In general however some overall preferences seem to exist. In many structures the guanidine group of an arginine makes bidentate hydrogen bonds with the edge of a guanine base, and glutamine is a frequent contact point in the recognition of adenine bases, also through double hydrogen bonds. In addition, many examples are described of van der Waals contacts between hydrophobic side chains and the 5-methyl group in thymine.\(^4\)

### 1.1.3 Structural Changes Induced by Complex Formation

When a protein binds specifically to a DNA sequence element, it is not uncommon to observe induced changes in the local structure of DNA. These changes can be a bending of the DNA duplex, alterations in twist and roll angles, and changes in groove width.\(^17\) How easily a given DNA segment will undergo the induced changes will depend on its sequence. AT-rich tracks will for example prefer to undergo bending that compresses the minor groove, while GC-rich tracks will prefer kinks that make the major groove more narrow. These differences in deformabilities have as consequence an indirect sequence dependence of protein–DNA complexes that comes in addition to hydrogen bond formation.\(^18\) The asymmetrical neutralization of charge by a protein bound along one side of the DNA helix will by itself cause some bending.\(^19\) In addition, architectural factors interact with DNA through minor groove contacts and alter DNA conformation in a more dramatic way.\(^20\) Protein-induced bending in the binding site can very easily be analyzed by versions of the EMSA method described below.

It has been realized that many proteins also undergo conformational changes upon DNA binding. Part of the DNA-binding surface will in these cases be generated during the interaction. The thermodynamics of the ‘induced fit’ model for DNA recognition, where local folding is coupled to binding, have been treated in detail by Spolar and Record.\(^21\) Recently it was proposed that specific binding sites bound by a transcription factor might in fact act as a ligand for the protein capable of inducing distinct conformations in the factor, some activating and others repressing.\(^22\) In this view, the DNA-induced conformational changes in the transcription factors could be central to their functional output, and these factors can be regarded as true information-processing proteins.

### 1.2 Protein–RNA Interactions

The specific recognition of RNA by a protein has many distinct features.\(^7,23–26\) At the level of shape recognition, RNA recognition differs considerably from DNA recognition. RNAs are generally single-stranded molecules that are intramolecularly folded into defined 3D structures of great variety. Even in stem regions RNAs have distinct structures since the presence of a 2'-hydroxyl group in RNA causes the duplex segments to be close to A-form DNA. Hence, protein interactions in duplex regions often occur through the wide accessible minor groove. Also induced fit and rearrangements of the RNA structure by the bound protein are common themes in protein–RNA interactions. At the level of chemical recognition, many of the principles of protein–DNA interaction also apply to protein–RNA interactions.

### 2 METHODS USED TO MONITOR PROTEIN–OLIGONUCLEOTIDE INTERACTIONS

Two electrophoretic methods dominate the analysis of protein–DNA interactions. EMSA is technically the simplest and is used in its basic form to reveal sequence-specific DNA-binding activity in a protein sample or cell extract. Here complex formation generates a separate migrating band in a nondenaturing gel, and the protein–DNA binding thus leads to generation of a positive signal. The same method is also called band shift assay, gel retardation assay, gel shift assay or gel mobility shift assay (GMSA). A footprinting method provides more detailed information on the precise location of a bound protein along the DNA fragment. Here binding lead to removal of specific bands (negative signal) in a pattern of cleaved fragments separated by electrophoresis and reflecting the sequence of the DNA. Both methods are highly sensitive due to the use of radioactively labeled oligonucleotides that enable detection and analysis of proteins in the femtomole range. Both methods can be performed with protein samples of low purity. Since their specificity resides in the DNA sequence, they both require some prior knowledge of the sequence around the binding site. When combined these methods are capable of providing a picture of the protein–DNA complex with a great deal of molecular detail, surpassed only by the more demanding methods of crystallography and NMR.

### 2.1 Electrophoretic Mobility Shift Assay

In EMSA the complex that is formed between a sequence-specific DNA-binding protein and its recognition sequence (encoded by a duplex oligonucleotide or
Figure 1 Schematic representation of the basic principle of the EMSA.

a DNA fragment) is subjected to electrophoretic separation in a nondenaturating polyacrylamide (PA) gel. Since the complex is fairly stable, the macromolecules remain associated during electrophoresis. In its standard version the duplex oligonucleotide is radioactively labeled and its migration is detected after electrophoresis by autoradiography. Unbound DNA is seen as the fastest migrating band, while complex formation leads to bands of reduced ("shifted") mobility, hence its name. This principle is illustrated in Figure 1. This simple method was first described by Fried and Crothers and by Garner and Revzin, and has now become one of the standard methods in molecular biology. It has been the subject of several reviews.

2.1.1 Principle of Electrophoretic Mobility Shift Assay

During EMSA both free and bound DNA migrate towards the positive pole driven by the dominating negative charge of the oligonucleotide. The shifted mobility of the complex is caused mainly by two effects. Neutralization of several phosphate groups in the oligonucleotide by basic residues in the protein leads to a reduced net negative charge of the complex compared to free DNA. In addition, the increased mass of the complex caused by the added protein will affect migration. Both these contributions work in the same direction to slow the migration of the complex. Which of these effects dominate depends on the specific proteins under study and experimental conditions used. Even small DNA-binding domains, with a size that barely contributes to retardation in a 6% PA gel, may give well shifted complex bands, suggesting that the neutralization of charge can make a major contribution to the shift in mobility (see Figure 2). The effect of molecular mass can be seen in the analysis of truncations of the same DNA-binding protein. When the mass of the protein increases, the migration is normally retarded as illustrated in Figure 2 (compare lanes 1 and 2). On the other hand, when the mass of the oligonucleotide increases, the shift in migration may be reduced since the relative mobility of bound versus free DNA tends to increase with increasing oligo length. Hence, it has been concluded that it is the ratio of protein and nucleic acid masses rather than their absolute mass which is important for resolution in EMSA. The contribution of the associated protein will of course be one of both mass and charge. The latter can be illustrated by an EMSA analysis of mutants of the same c-Myb-derived protein (Figure 2). On a 6% PA gel, where the effects of differences in masses are expected to be negligible, a clear effect of charge differences can be seen. When a mutation eliminates a positive charge (R102A, lane 4) or adds a negative charge (V117D, lane 6), the complex migrates slightly faster, while the introduction of an extra positive charge (T96R, lane 3) or elimination of a negative charge (E105A, lane 5) have the opposite effect and cause slower migration. The importance of the charge effect is best illustrated by the E105A protein (lane 5), which migrates slower due to its reduced charge even if its mass is reduced by 58 Da. An interesting use of this phenomenon

Figure 2 DNA-binding of recombinant c-Myb proteins analyzed by EMSA. DNA-binding was monitored by the EMSA using purified chicken c-Myb-derived proteins expressed in E. coli (Protocol 4) and a labelled MRE(mim) oligonucleotide as DNA-probe (using Protocols 1B, 2, and 3A). Each binding reaction contained 20 fmoles of recombinant protein and 10 fmoles labelled oligonucleotide and the analysis was performed as described in Protocols 6 and 7. On the autoradiogram shown C1 indicates the complex formed with a protein spanning the three domains R1, R2, and R3 in c-Myb (residues 39–192, protein of 18.8 kDa) (lane 1), while C2 indicates the complex formed with the smaller protein containing only the R2 + R3 domains (residues 89–192, wild type protein of 12.7 kDa) (lane 2–6). In addition to the wild type version of R2R3 (lane 3), four mutants of the same protein were used: T96R, R102A, E105A and V117D (lanes 3–6). Lane 7 shows the free DNA-probe only.
is in studies of phosphorylation of DNA-binding proteins where the altered charge may be followed by mobility changes in EMSA (see below). A third factor that also will affect the migration of the complex is its conformation, a phenomenon that is directly exploited to study protein-induced conformational changes in DNA (see below).

It has been suggested that protein–DNA complexes may in fact be stabilized by the PA matrix itself. This phenomenon termed “caging” was interpreted as an effect of the gel matrix that impeded the diffusion and separation of the dissociated components. Concentrations of protein, DNA and complex would thus remain high, close to the migrating complex favoring reformation of complexes after dissociation.

For a more extensive discussion of theory and principles of EMSA, see the recent review by Cann.

2.1.2 Usage of Electrophoretic Mobility Shift Assay

The attractiveness of EMSA lies both in its simplicity and its wide range of applications. Its potency is illustrated as follows.

EMSA is used to assay for the presence of a particular sequence-specific DNA-binding protein in cell extracts. EMSA is widely used in combination with nuclear extracts (NE) obtained from cultured cells. The potency of the method lies in its ability to assay several different protein factors in the same extract simply by changing the duplex oligonucleotide. In a crude cell extract it is usually important to confirm the specific nature of a shifted band either by competition experiments or by performing a supershift experiment as discussed below.

EMSA is used to follow the purification of a particular sequence-specific DNA-binding protein. For several proteins like transcription factors, this is often the only simple in vitro assay available that is specific for the factor and applicable to rapid screening of fractions.

EMSA is used to analyze the effect of mutants in the DNA-binding domain of a specific protein. Mutations that have a significant effect on DNA-binding can easily be identified in EMSA studies.

EMSA can also be used to analyze the effect of protein modifications (phosphorylation, oxidation etc.) on DNA-binding of a specific protein. Again, alterations that have a significant effect on DNA-binding can easily be identified. Even modifications that do not reduce or increase DNA-binding can be observed if they lead to an alteration of charge, as in cases of phosphorylation. Since a phosphate group will contribute both with a small increase in size and a negative charge (working in opposite directions with respect to migration), it may be necessary to optimize the running conditions to get a maximum effect of either the charge difference or the increased mass in order to get a separate band for the modified form (low/high gel concentration and extended running times). By using a series of systematically mutated duplex oligonucleotides, EMSA can be used to analyze the importance of each base pair in the binding site for a particular DNA-binding protein. Similarly, related but different response elements found in different genes can be systematically compared with EMSA. See Stormo and Fields for a recent discussion of this topic.

EMSA with purified proteins can be used to determine thermodynamic binding constants for complex formation. Even if EMSA separates the components in the binding reaction after equilibrium is obtained, it is generally assumed that what is observed after electrophoresis reflects equilibrium concentrations in the binding reaction before loading on the gel. The caging effect discussed above is probably one reason why this seems to be a good approximation in many cases making it possible to obtain reasonable estimates of equilibrium constants from EMSA. Quantitation of the unbound DNA and the protein–DNA complex (by phospho-imager, by scanning of the autoradiogram or by direct scintillation counting of excised bands) provide concentration information on two of the three components in the simple equilibrium reaction (Equation 1):

\[ P + dO = C \]

where \( P \) is the equilibrium concentration of unbound DNA-binding protein, \( dO \) is the equilibrium concentration of unbound duplex oligonucleotide, and \( C \) is the equilibrium concentration of the protein–DNA complex. The information provided by EMSA-quantitation is \( C \) and \( dO \). Then the equilibrium constant is given by Equation (2)

\[ K_{app} = \frac{[C]}{[P][dO]} \]

A simple estimate of binding constant can be made from a series of binding reactions with increasing protein input (or decreasing probe input). Typically, the ratio of bound to unbound (\([C]/[dO]\)) DNA is determined at several concentrations of protein and then curve-fitting is employed to give an estimate of \( K_{ass} \) (or \( K_d \)). Scatchard plot is one convenient way of plotting the data for curve fitting (plotting \([C]/[dO]\) versus \([C]\)). A very simple alternative is the following. At the input where the retarded band and the unbound oligonucleotide becomes equal in intensity on the autoradiogram, the following simplification can be made (Equation 3):

\[ K_{app} = \frac{1}{[P]} \]

\([P]\) can then be calculated from Equation (4):

\[ [P] = P_0 - [C] \]
where P indicates the total input of purified protein. More sophisticated approaches have been reviewed.\textsuperscript{(39,31,32,43,44)}

EMSA can also be used to estimate kinetic parameters by loading samples from a binding reaction on a running EMSA gel.\textsuperscript{(32)} Again, the underlying assumption is that the electrophoresis “freezes” the ratios of the components at the time of entrance into the gel matrix.

EMSA can also be used to analyze the assembly of multiprotein complexes, to demonstrate synergistic assembly of complexes where two or more protein factors bind closely positioned sites or where macromolecular assemblies are formed with only one DNA-binding component. If the original DNA probe is large enough to cover several binding sites, and a complex pattern of shifted complexes is observed, these may be analyzed by competition with distinct duplex oligonucleotides representing individual binding sites for specific transcription factors. Cooperative assemblies of protein–DNA complexes have been recently reviewed.\textsuperscript{(45)}

Even if the most common use of EMSA is analytical with sensitive labeled probes, the method can also be used preparatively to isolate a particular sequence-specific DNA-binding protein from a partially purified sample.\textsuperscript{(46)}

EMSA is often performed with a specific antibody added to demonstrate the presence of a previously identified DNA-binding protein in the complex. This is of particular importance when analyzing crude cell extract preparations where a shifted band may be caused by factors other than that expected. Most EMSA protocols can easily be adapted to this type of analysis simply by allowing the antisera and the protein sample to be pre-incubated for about 30 min on ice before proceeding with the DNA-binding reaction. Addition of antibodies may either block complex formation, if the epitope recognized is one critical for DNA-binding, or lead to a complex with reduced mobility, if the epitope recruits the antibody to the complex without affecting protein–DNA interaction. The latter is generally called “supershift” and is the result that is the simplest to interpret. In these kinds of experiments, two types of controls are desired: analysis of the antisera alone in EMSA and a “supershift” control with an unrelated antibody or pre-immune serum, both to exclude artificial nonspecific bands.

Since the DNA-binding function of a protein often resides in a small domain representing only a fraction of the protein’s molecular mass, it is possible to subject a protein to limited proteolysis and thus generate a fingerprint pattern of digestion products and analyze these in EMSA. All fragments with the DNA-binding domain untouched should normally give shifted bands, but these will migrate differently due to their different masses. The digestion pattern will provide a unique fingerprint pattern characteristic of the protein in question and can be used for comparative purposes. Protocols for this “proteolytic clipping band shift assay” are found in Dent and Latchman.\textsuperscript{(35)}

Several transcription factors induce bending and other conformational changes in DNA upon binding (as referred to above). When a protein induces a bend in the DNA helix, this may result in changes of mobility of the complex during electrophoresis in a way that depends on the bend position within the migrating DNA fragment.\textsuperscript{(17,30,32,37,47)} By using a series of fragments of equal size, but with the protein binding site differently located along the fragments (circular permutation), it is possible, using EMSA, to demonstrate induced bending from the position-dependent migration of the complexes. It is even possible to estimate the bending angle. In addition, by combining with a static sequence-induced bend it is possible to determine the direction of the protein-induced bend (phasing analysis). These methods are normally performed with restriction fragments of DNA (generated from plasmids designed for the purpose\textsuperscript{(48,49)}), rather than with oligonucleotides. Information on these techniques can be found in several reviews.\textsuperscript{(18,47,50–53)}

### 2.1.3 Practical Aspects of Electrophoretic Mobility Shift Assay

To set up a standard EMSA experiment, the following steps have to be performed:

- preparation of oligo probe
- preparation of protein sample
- making of the PA gel
- performing the binding reaction
- electrophoresis
- autoradiography.

In the following paragraphs, these steps will be described and commented on.

### 2.1.4 Preparation of Labeled Oligo Probe

There are several possibilities to label an oligonucleotide for use in EMSA. Usually, the oligonucleotide is labeled by \(^{32}\)P on one or both ends of the duplex. In contrast to footprinting probes, the location of label is not critical for binding probes used in EMSA. Since commercially synthesized oligonucleotides generally are delivered with a 5'-OH, they are ideal substrates for T4 polynucleotide kinase. This kinase will transfer the labeled γ-phosphate from [γ-\(^{32}\)P] adenosine triphosphate (ATP) to the 5'-end of the oligonucleotide leading to a probe with high specific activity (>1000 cpm/fmol). In our lab we routinely use the Ready-To-Go\texttrademark T4 Polynucleotide Kinase kit (Pharmacia) to label up to 10 pmole oligo,
but a standard reaction mix will work as well for this purpose (see Protocols 1A and 1B). Since the enzyme is more efficient with single-stranded termini than with blunt ends, it is recommended to first kinase the oligonucleotide and then to anneal it to the second complementary oligonucleotide to generate the duplex probe. A fast method to prepare EMSA probes is to kinase the first oligonucleotide, anneal it with a slight molar excess of the complementary oligonucleotide (to force quantitative annealing of the labeled strand) and purify the duplex by a spin column to eliminate unincorporated isotope and buffer components. This can be performed in a few hours. To obtain good, clean EMSAs and for more critical experiments, in particular more quantitative experiments, it is recommended to purify the duplex on a PA gel. For quantitation of $^{32}$P-incorporation it is advocated to take a small aliquot of the kinase reaction, mix it with carrier tRNA, spot half on a 3MM paper filter disk that is dried (total cpm), the other half on a filter disk that is precipitated and washed in cold 10% trichloroacetic acid (TCA) (incorporated cpm). After scintillation counting, it is then possible to calculate the efficiency of labeling and the specific activity of the probe (cpm or dpm per fmole oligonucleotide). After purification, an aliquot of the final probe is also counted. From these values (specific activity and activity in final probe) it is easy to calculate the recovery and final molar concentration of the probe.

If several EMSA probes are needed with the same specific activity, it is possible to design the different oligonucleotides such that they all contain a common sequence in the 3' end (approximately 10 nucleotides). A small oligonucleotide complementary to this common region is then labeled first, and thereafter annealed to the different oligonucleotides followed by a fill-in reaction using DNA polymerase I (DNase I) (Klenow fragment) and the four deoxyribonucleotide triphosphates. In this manner, all probes get identical specific activities and therefore directly comparable intensities in EMSA.

As an alternative to use of T4 polynucleotide kinase, the two oligonucleotides needed to generate a duplex can be designed to generate a 5’-protruding single-stranded terminus after annealing. Such a duplex will be a template for a fill-in labeling using DNase I (Klenow fragment) and the relevant $[^{32}P]$ deoxyribonucleotide triphosphate. Advantages of this approach are the possibility to incorporate more than one $^{32}$P-labeled nucleotide and to incorporate unlabeled nucleotides after the labeled one and thus obtain a probe where the $^{32}$P is better protected toward enzymatic degradation. Degradation of the label in crude cell extracts may be a problem reducing the sensitivity of the assay. In general, a duplex oligonucleotide of 20–30 base pairs will be sufficient for EMSA. If larger fragments are needed, these may be isolated as restriction fragments that can be labeled by fill-in as described above, or produced as polymerase chain reaction (PCR) fragments. In the latter case, labeling is achieved either by kinasing of the PCR primer(s) or by including an [$^{32}$P] deoxyribonucleotide triphosphate in the PCR reaction.

### 2.1.4.1 Protocol 1A: Labeling Oligonucleotides by Polynucleotide Kinase

- Decide the amount of oligonucleotide to be labeled, and calculate the equivalent amount of [$^{32}$P]-ATP isotope. A standard isotope with specific activity of 3000 Ci mmole$^{-1}$ and a concentration of 10 µCi µL$^{-1}$, will have an ATP concentration of 3.3 pmol µL$^{-1}$. Using a slight excess of isotope, 10 pmol oligo requires 3.5–4 µL [$^{32}$P]-ATP isotope.
- Mix in a PCR tube on ice the following (add enzyme last):
  - 1.0 µL 10 µM oligonucleotide (single-stranded)
  - 3.5 µL [$^{32}$P]-ATP 3000 Ci mmole$^{-1}$
  - 1.0 µL 10× polynucleotide kinase buffer
  - 1.0 µL 10 U µL$^{-1}$ polynucleotide kinase
  - 3.5 µL H$_2$O
- Incubate at 37°C for 45 min, followed by enzyme inactivation at 65°C for 10 min.
- Remove an aliquot of 1 µL for scintillation counting and estimation of incorporation, as follows:
  - Mix the 1-µL aliquot with 25 µL 2 mg mL$^{-1}$ tRNA.
  - Spot 12 µL of the mixture on one 3MM paper circle disk and leave to dry.
  - Spot 12 µL of the mixture on another 3MM paper circle disk and put it into a vessel of ice-cold 5% TCA.
  - Wash with gentle shaking for 5 min, pour off and repeat washing three times with 5% TCA.
  - Dry the filter disks.
- Put the two filters into scintillation vials, add 5 mL of water and count incorporation using the $^3$H channel of the scintillation counter. Take 1-µL aliquots of the final purified probe, spot, dry and count similarly. Use the cpm values and concentrations to calculate specific activity of the probe.

### 2.1.4.2 Protocol 1B: Labeling Oligonucleotides by Ready-To-Go™ PNK-kit

- Add 25 µL H$_2$O to one tube from the Ready-To-Go™ PNK-kit (Pharmacia) containing freeze-dried
material. Leave it for 2–5 min at room temperature to allow solubilization, and then mix by gentle pipetting.

- Transfer the mixture to a PCR tube to allow the incubation and subsequent annealing to be performed in a PCR machine.
- Add the following to the tube:
  - 1.0 µL 10 mM oligonucleotide (single-stranded)
  - 3.5 µL [γ-32P]-ATP 3000 Ci mmole⁻¹
  - 20.5 µL H₂O
- Incubate the mixture for 30 min at 37°C.
- If no fill-in reaction is necessary, stop the reaction by addition of 2 µL 0.5 M ethylene diamine tetraacetic acid (EDTA). If fill-in is required, no EDTA must be added at this stage.
- Remove an aliquot of 3 µL for scintillation counting and estimation of incorporation (see Protocol 1A).

2.1.4.3 Protocol 2: Annealing to Complementary Strand and Rapid Purification

- The PCR tube with the kinasing mixture (Protocol 1B) can be processed directly. If protocol 1A is used, transfer the kinasing mixture to a PCR tube and adjust the protocol to the amounts and volumes used.
- Add a slight excess of oligonucleotide that is complementary to the kinased oligo. 50% excess usually works well. The ionic strength is increased by addition of NaCl to facilitate annealing. Following the protocol 1B this means the following addition:
  - 1.5 µL 10 mM complementary oligonucleotide (single-stranded)
  - 5 µL 5 M NaCl
- Incubate in a PCR machine at 70°C for 5 min, followed by a programmed slow decrease in temperature (one degree per minute) until the temperature has dropped to below room temperature.
- If the oligos that have been annealed are equal in length, the duplex probe is ready for purification (proceed with protocol 3A or 3B). If a shorter primer oligo has been labeled and annealed to a longer complementary oligonucleotide, a fill-in step is required at this stage to produce a full-length duplex.

- Optional fill-in reaction. Add the following to the tube on ice:
  - 2 µL 5 mM dNTP (mixture of dGTP, dATP, dTTP and dCTP; 5 mM each)
  - 0.5 µL 5 U µL⁻¹ DNaseI Klenow-fragment.
- Incubate on ice for 2 min, followed by incubation for 45 min at 15°C.
- Stop the reaction by addition of 2 µL 0.5 M EDTA.

2.1.4.4 Protocol 3A: Rapid Purification by Spin Columns

- Duplex oligo probes can be rapidly purified from unincorporated nucleotides by a spin column version of gel filtration. Suitable for this purpose are the MicroSpin G-25 Columns (Pharmacia). The disadvantage with this rapid method relative to purification on PA gels, is that the purified probe will still contain some labeled oligonucleotides that have not been annealed to duplex form, as well as the remaining complementary oligonucleotide.
- Follow the instructions of the kit for preparing the column, and load carefully 25–50 µL of the kinasing reaction on the column. Spin according to the instructions given by the manufacturer.

2.1.4.5 Protocol 3B: Purification on Polyacrylamide Gels

- Assemble the glass plates for the electrophoresis unit. The recipe below is for a 20 × 20 × 0.1 cm PA gel.
- To make a 15% PA gel, mix the gel solutions in a vacuum flask:
  - 11.25 mL 40% acrylamide [C₂D₂: 7% (relative concentration of bis/bis + acrylamide)]
  - 0.6 mL 1 M Tris–HCl, pH 8.0
  - 18 mL H₂O.
- Degas and start polymerization by adding:
  - 100 µL 10% APS (ammonium persulfate)
  - 20 µL TEMED (N,N,N’,N’-tetramethylenediamine).
- Pour the gel solution immediately between the plates and mount the well-forming comb.
- Use as electrophoresis buffer 20 mM Tris–HCl, 0.1 mM EDTA:
  - 20 mL 1 M Tris–HCl, pH 8.0
  - 0.2 mL 0.5 M EDTA
  - H₂O to 1000 mL.
- Run a pre-electrophoresis at 250 V for 15–30 min.
- Add a blue marker to the labeled oligos, and load each of them in 1–3 lanes.
- Perform the electrophoresis at 15 V cm⁻¹ until the marker has migrated two-thirds of the length of the gel.
- While the electrophoresis is running, prepare three small adhesive pieces of paper (3 × 3 mm) and spot 0.5–1.0 µL of any radioactive solution of suitable
activity. Allow to dry. These will be used for orientation purposes. Alternatively, special fluorescent paper strips may be used.

- Stop the electrophoresis and remove one of the glass plates. Attach the three adhesive papers to the other glass plate in an asymmetric pattern around the gel. Wrap in plastic film and place an X-ray film over the gel in the dark room. Expose for 3–5 min, or longer for weaker probes. Develop the film.

- By alignment of the paper spots to the corresponding spots on the film, it is possible to precisely orient the gel over the film. Cut out the labeled oligos and place them in a microcentrifuge tube. Add 1 mL 10\% TE-buffer [1 mM Tris–HCl (pH 8.0), 0.1 mM EDTA] and place the tubes in a rotating device (like a hybridization oven) at 37 °C overnight.

- Next day, transfer the eluate to a new tube. Spin briefly the tube with the gel to collect all the liquid. Spin the tube with the pooled eluate in a benchtop centrifuge for 1 min and transfer the eluate carefully to a new tube leaving behind the last 10–20 µL to avoid traces of gel pieces.

- Concentrate the eluate with 2-butanol as follows. Add 500 µL 2-butanol, vortex and spin for 1 min to separate the phases. Remove the upper phase of 2-butanol. Add a second portion of 500 µL 2-butanol, vortex and spin. Remove the upper phase of 2-butanol. Continue this extraction procedure until the volume of the lower water phase is reduced to 100–150 µL. Carefully remove traces of 2-butanol.

- Spot three aliquots of 1 µL on a 3MM filter paper disk, dry and count to determine the activity and concentration of the final probe.

2.1.5 Recombinant Proteins as Protein Source

When the DNA-binding properties of a specific DNA-binding protein are to be characterized, it is advantageous to express the protein of interest in bacteria or another system for efficient production of recombinant protein. The DNA-binding function in proteins like transcription factors often resides in a small independent domain of the protein. In cases where it is difficult to express a soluble functional full-length protein, it is possible to express only a subdomain carrying the full DNA-binding function of the protein. Smaller DNA-binding domains will often be soluble in E. coli and expressed more efficiently than larger proteins. Many commercial systems for expression of recombinant proteins in E. coli are available, generally using vectors that allow the inductive expression of tagged proteins that are easy to purify in a single step on affinity resins. Tags (like glutathione S-transferase (GST), His-tags, etc.) are in most cases very useful, but it should be verified that a particular tag does not alter the DNA-binding affinity or properties of a protein. In our work with the c-Myb DNA-binding domain, we have observed 10–100-fold reductions in binding constants due to fusion to tags. If the tag is only used for purification purposes, it should also be noted that unfused DNA-binding domains overexpressed in E. coli may be very easy to purify by more classical approaches. Columns of choice are either a negatively charged heparin matrix (like Heparin-Sepharose or HiTrap, Pharmacia) or classical cation exchangers (S-Sepharose). The efficiency of these matrices is probably due to the presence of a basic domain in DNA-binding proteins able to bind efficiently to the negative phosphodiester chain in DNA and hence also with high affinity to cationic matrices. In addition, E. coli appears to produce few basic proteins at comparable high levels that will contaminate the actual fractions. In our experience, it is possible in a one-step procedure to obtain in the order of 90% pure recombinant proteins in this way, and if the two types of columns are combined, a very high purity can be obtained without the need of any tags.

DNA-binding studies with purified recombinant proteins is recommended when well-defined and quantitative biochemical experiments are to be performed, since a precise estimation of protein concentrations is possible. On the other hand, the specificity of EMSA allows detection of specific DNA-binding proteins expressed in E. coli directly in a cell-free extract obtained after induction, lysis and high-speed centrifugation of the cell lysate. In crude systems it is important to include a nonspecific DNA like poly dI–dC competitor to eliminate interference from nonspecific DNA-binding proteins. If only analytical quantities are needed to demonstrate a particular protein–DNA interaction, an alternative approach is to use coupled in vitro transcription/translation systems.

An obvious disadvantage of expression of mammalian protein in bacteria is of course the lack of post-translational modifications. Properties deduced from in vitro experiments with recombinant proteins should therefore be validated by studies of the same protein in NE from relevant cells where modifications may be expected to occur.

2.1.5.1 Protocol 4: Purification of Untagged Recombinant DNA-binding Proteins Expressed in E. coli

- The DNA-binding protein or subdomain is expressed in E. coli BL21(DE3) LysS using the T7 system (or other commercial systems). Recombinant E. coli cells are grown in SOB medium (20 g L\(^{-1}\) bactotryptone, 5 g L\(^{-1}\) bacto-yeast extract, 0.5 g L\(^{-1}\) NaCl, 2.5 mM KCl, pH 7.0; before use add 20 mM MgSO\(_4\)) at 37 °C to an optical density of 0.6–0.9 and then induced by addition of isopropyl-β-D-thiogalactopyranoside ((IPTG), final concentration...
0.4 mM). The cells are harvested after two hours of induction, washed once in cold TEN buffer (10 mM Tris–HCl, 1 mM EDTA and 100 mM NaCl), and resuspended on ice in buffer A (20 mM Tris–HCl, pH 8.0, 1 mM EDTA, 10% glycerol, and 1 mM dithiothreitol (DTT)) containing 500 mM NaCl. To the suspension on ice is added phenylmethylsulfonyl fluoride (PMSF, 1 mM), and Triton X-100 (0.1%). After lysis (5–10 min), the viscous suspension was centrifuged at 40,000 rpm for 1 hr in a TFFT 65.13 rotor at 4 °C. The nonviscous part of the supernatant is collected. At this stage, the extract may be stored at −80 °C.

- The proteins can then be purified on a heparin affinity column using a buffer containing 20 mM Tris–HCl, pH 8.0, 1 mM EDTA, 10% glycerol, 1 mM DTT, 0.01% Triton X-100 and 0.1 mM PMSF. The samples are loaded on the column using 250 mM NaCl (this may be adjusted for each protein), and the proteins are purified in an NaCl gradient from 250 to 1500 mM.

### 2.1.6 Nuclear Extracts or Whole Cell Extracts as Protein Source

By far the most common use of EMSA is to demonstrate the presence of a particular DNA-binding activity in an extract from a particular cell line or from a tissue. Identification of the pattern of endogenous transcription factors expressed in a particular cell type is an important step in the characterization of a promoter active in that cell line. Alternatively, a cell line may be transfected with expression plasmids for a particular DNA-binding protein resulting in higher levels of the protein of interest. The preparation of extracts for EMSA may be performed from entire cells giving whole cell extracts (WCE) or from isolated nuclei giving NE. The advantage of WCE is a simpler procedure with fewer steps where loss of activity can occur. In cases where a DNA-binding protein shuttles between cytoplasm and the nucleus, a WCE may also reflect the whole DNA-binding capacity of the cell in question. The disadvantage is mainly one of lower relative abundance since nuclear proteins become diluted with a large amount of cytoplasmic proteins. It is also the only option when the cellular material has been frozen, since this destroys the nuclear membrane and precludes the isolation of nuclei. If sufficient cell material is available, it may be advantageous to prepare a nuclear extract. Several protocols are available for this most of them derivatives of the original protocol of Dignam et al. Assemble the glass plates for the electrophoresis unit. Mix the gel solutions in a vacuum flask:

- 4.5 mL 40% acrylamid [C = 2.7 (relative concentration of bis/bis+acrylamide)]
- 3.0 mL 5× TBE [0.45 M Tris-base, 0.45M boric acid, 10 mM EDTA]
- 3.0 mL 50% glycerol
- 19.5 mL H2O

Degas and start polymerization by adding:

- 150 μL 10% APS
- 20 μL TEMED.

Pour the gel solution immediately between the plates and mount the well-forming comb. Use 0.5× TBE as electrophoresis buffer. When the gel has polymerized, remove the comb and the bottom spacer and mount in the electrophoresis unit. After the electrophoresis buffer has been filled up, wash the wells with buffer.

Since the samples to be loaded are without color, it might be practical to mark the wells on the outside by a permanent ink pen.

To avoid dissociation due to heating during electrophoresis, place the gel apparatus in the cold room.

### 2.1.7 Protocol 6: Preparation of Polyacrylamide Gel

1. Cells are seeded in 10-cm dishes at a density of 5 × 10⁵ per plate and transfected with 30 μg of DNA per plate. Cells are harvested 36 h after transfection in 500 μL of F buffer [10 mM Tris–HCl (pH 7.05) 50 mM NaCl, 30 mM sodium pyrophosphate, 50 mM NaF, 5 μM ZnCl2, 100 μM Na3VO4, 1% Triton X-100, 1 mM PMSF, and a cocktail of protease inhibitors].

2. The lysate is vortexed for 30 s before centrifugation at 14,000 rpm for 30 min at 4 °C. The supernatants are stored as aliquots at −80 °C after being rapidly frozen in liquid nitrogen.

3. For EMSA, use 1–3 μL as protein source.

### 2.1.8 Conditions for Complex Formation

The optimal conditions for complex formation will to some extent depend on the protein under study and...
should be optimized in each case. Some general guidelines may be followed. Many of the typical additions to enzymatic reactions (like buffer, salt, glycerol) will also help to keep a DNA-binding protein active. A comment should be made on the ionic strength in the reaction mixture (adjusted by the addition of salt). The latter is important for the stability and half-life of the complex. Since low ionic strength will stabilize protein–DNA interactions in general, too low salt concentration may strengthen binding to nonspecific sites as well (like on competitor DNA) and slow the exchange between specific and nonspecific sites. If the competitor is added to the protein before the probe under such conditions, the protein may remain associated with the competitor hampering specific complex formation. Too high ionic strength will on the other hand destabilize protein–DNA binding and preclude specific complex formation. It should also be noted that the ionic strength normally drops when the complex migrates into the gel matrix, a factor that contributes to the high stability and slow dissociation of the complex during electrophoresis. This is also the reason why EMSA is not ideal to measure the salt-dependence of protein–DNA complexes.

Some DNA-binding proteins may need specific cofactors to be active. Typical examples are the family of zinc finger proteins that require zinc to form an active DNA-binding structure. Addition of EDTA here can inhibit the activity of the factor. Many transcription factors contain easily oxidized cysteine residues in their DNA-binding domains. Addition of reducing agents like DTT or β-mercaptopethanol will be necessary to obtain full activity.

Due to the sensitivity of EMSA, operating below the picomole range of protein input, it may be necessary to take precautions to avoid adsorption of proteins to surfaces that may cause loss of active material. This is particularly important when working with purified proteins, and additions of non-ionic detergents (like NP-40 or Triton X-100) and/or inert proteins (like bovine serum albumine) are recommended.

Since the protein sample is the most fragile ingredient, we prefer to add this as the last part of the reaction mixture. After mixing the reaction components, they are usually incubated for a specific time at a specific temperature. Many complexes form very rapidly and extended time of incubation is not necessary. Incubation on ice may be sufficient. In some cases the binding may be a two-step reaction where a rapid bimolecular association is followed by a slower docking reaction involving conformational changes and leading to more stable complexes. In such cases incubation for 10–30 min at room temperature may be preferentially to obtain stable complexes.

A typical reaction mixture contains sufficient glycerol to be loaded directly on the gel after incubation. The addition of tracking dye before loading is not generally recommended since the dye may inhibit the binding activity of specific proteins. Loading dye may be added to a reference lane containing the probe only in order to follow the electrophoresis.

2.1.8.1 Protocol 7: Mixing Samples and Electrophoretic Separation of Complexes

- Estimate the amount of labeled probe and protein to be used in the binding reaction. Using the labeling protocol described above, a specific activity in the order of 1000 cpm fmole−1 should be attained and 10 fmol of duplex probe will be sufficient per lane to give strong signals on the autoradiogram after overnight exposure. The amount of protein input required depends on its binding strength and purity. With purified recombinant proteins 10–50 fmol will usually be sufficient. With WCE 1–2 µL is recommended.

- Dilute the protein/protein extract in an appropriate buffer on ice [like TGEDT500 (20 mM Tris–HCl, 10% glycerol, 1 mM EDTA, 500 mM NaCl, 1 mM DTT and 0.05% Triton X-100) with DTT and Triton freshly added]. The proteins should be freshly diluted and not stored in diluted form.

- Keep all samples on ice.

- Prepare the required number of tubes with the components added in the order listed below, giving a total reaction volume of 20 µL. Make one tube without added protein (free probe).
  - 4 µL 5× binding buffer (100 mM Tris–HCl, 50% glycerol, 5 mM EDTA)
  - 1 µL 0.5 mg mL−1 poly dI-dC (input adjusted depending on the protein purity, not necessary for pure recombinant proteins)
  - 12 µL H2O
  - 1 µL of duplex probe diluted to 10 fmol µL−1
  - 2 µL diluted protein/protein extract (giving a final [NaCl] = 50 mM).

- Incubate for 15 min at 25 °C (or on ice, see text).

- Assemble the electrophoresis apparatus, and place it in the cold room. Start the pre-electrophoresis (10 min at 200–250 V).

- Add a blue marker only to the lane with free probe (Coomassie Brilliant Blue, no detergent) to follow migration and to orient the gel later on.

- Load the samples in the respective lanes.

- Perform the electrophoresis at 10–20 V cm−1 for the required time (we use 200 V for 2 h; this will depend on the size and design of apparatus).
2.2 DNA Footprinting Methods

The information provided by EMSA is basically whether a DNA-binding protein recognizing part of the oligo sequence is present in a protein sample or not. It does not tell exactly what part of the sequence is recognized by the protein, even if such information can be obtained indirectly by EMSA by using a series of mutant oligos. Information on the location of a bound protein along a DNA sequence can be obtained in great detail using one or several types of footprinting methods. Footprinting is a designation used on a set of methods that combine modification of a specific DNA (chemically or enzymatically) with binding to a sequence specific protein. The modified DNA is finally cleaved into a series of fragments that are separated with base pair resolution on a sequencing gel. Since the original DNA fragment or oligonucleotide is end-labeled on one strand, the analysis can be restricted to the fragments retaining this label. This generates a pattern of cleaved fragments where all have one labeled end in common and where the other end marks the site of cleavage, which is also a site of modification. In this “ladder” of bands, each cleavage product corresponds to a specific nucleotide in the DNA sequence. To precisely align the ladder of cleavage products to the DNA sequence, a Maxam–Gilbert type of chemical sequencing reaction is performed on the same labelled DNA fragment, and run in parallel alongside the cleavage products. By comparing the generated pattern in the presence and absence of the bound protein, it is possible to locate the protein relative to the DNA sequence. In some versions protein binding creates a clear zone free of bands in the ladder, and this region is usually called a “footprint”.

The size of a binding site for a typical sequence-specific DNA-binding protein varies, but will most often be in the range of 5–15 base pairs. Although DNA fragments of a few hundred base pairs have often been used in these kinds of analyses, the methods are easily adapted for use with duplex oligonucleotides of some length. In the design of oligonucleotides for footprinting, it should be taken into consideration that the binding site becomes situated at some distance from the end that is labeled (>25 base pairs). This is because most methods rely on the precipitation of DNA cleavage products, which becomes challenging when fragment lengths are too short. Labeling strategies for these methods are the same as for EMSA probes, but now only one end can be labeled. To fully analyze a region of interest by DNA footprinting, two probes should be prepared, each with one of the strands labeled.

Depending on the types of modifications used, the protein–DNA interaction can be mapped with different degrees of accuracy. Footprinting methods can be divided into two main groups, protection and interference types of footprinting, depending on the order of operations involved. Methods where protein binding precedes DNA modification are called protection footprinting methods, since these methods show at what positions the bound protein protects the DNA from subsequent modification reactions. Methods where DNA modification precedes protein binding are called interference footprinting methods, since these methods show at what positions a specific DNA modification interferes with subsequent protein binding. Although these methods were originally developed as in vitro methods, some of them have also been adapted to analysis of protein binding in vivo. Footprinting methods have been the subject of several reviews.

2.2.1 Protection Footprinting Methods

Protection footprinting involves treatment of a preformed protein–oligonucleotide complex with agents that modify the DNA. The specific methods vary with respect to the type of modification agent used. Their common feature is that they provide information on how sequence-specific protein binding affects subsequent DNA modification reactions in the binding site. The general principle of protection footprinting is illustrated in Figure 3.

An end-labeled duplex oligonucleotide or DNA fragment is allowed to bind to an excess of a specific DNA-binding protein so that the DNA is quantitatively complexed with the protein. A control without the protein is processed in parallel. Then the chemical or enzymatic agent is allowed to modify the complex and the control DNA. The agent will attack randomly, but will be excluded from certain positions along the DNA due to the presence of the protein. When the DNA finally is deproteinized and cleaved at the modified positions, followed by separation on a sequencing gel, the pattern of labeled bands will reveal at which positions the presence of the protein has protected against modification. From this information, the location of the bound protein can be deduced.
2.2.2 Footprinting using the Enzyme DNase I

DNaseI footprinting was the first DNA footprinting method developed\(^\text{72}\) and today is one of the most commonly used variants of protection footprinting. As the name implies, the modification agent here is the enzyme DNaseI. The complex is exposed to a fixed (titrated) amount of DNaseI for a brief period of time (15–60 s), which will introduce nicks in DNA in a fairly random fashion, but will be excluded from the region where the bound protein is located. This creates an open zone free of cleavage products indicating the position of the protein (a “footprint”). Because the enzyme introduces cleavages directly, no separate cleavage step is required, making this variant one of the simpler versions of protection footprinting methods. To obtain an optimal ladder of bands, it is important to find conditions that give a “single hit” pattern where the complexes on the average are only cleaved at one position. It is therefore recommended to carefully titrate the input of DNaseI under the reaction conditions to be used, to find the amounts of enzyme that give the best ladder of cleavage products. It is noteworthy in this context that DNaseI is highly sensitive to the ionic strength in the reaction mixture.

While simplicity is the major advantage, a few disadvantages of DNaseI footprinting should also be mentioned. The first is one of limited resolution. Since the cleavage agent is a protein of 31 kDa, it will easily be excluded by steric hindrance from the binding site by the bound protein. Although this generally contributes to a good visual footprint, the protected region will usually be slightly larger than the DNA region actually in direct contact with the bound protein. A related problem is that DNaseI does not cleave in a totally random fashion, but has some secondary structure preference. The consequence is an uneven pattern of bands and some regions may have few cleaved fragments, reducing the resolution of the footprint analysis.

Another problem common to most of the protection methods is that a bound protein produces negative signals, that is the disappearance of specific bands on a gel. To obtain a clear pattern it is therefore crucial to start with conditions where the labeled DNA is quantitatively complexed to the protein. If not, the footprinted zone will not be free of signals since the remaining uncomplexed DNA will be attacked and produce cleavage products in the zone. This is not necessarily a major problem if it is possible to scan the footprint and treat it quantitatively. In cases where it is difficult to obtain optimal conditions of binding, an improved footprint can be obtained by isolating the complex before deproteinization and denaturation. The DNaseI reaction can be stopped by EDTA and the nicked complex separated from free DNA using EMSA. The retarded complex band is cut out from the EMSA gel, eluted and then processed according to the standard DNaseI footprint protocol. In this way, only complexed DNA is analyzed. This latter version has been called “indirect” footprinting to distinguish it from the “direct” footprinting that lacks the EMSA step.

A phenomenon that is often observed, in particular in the border regions of a footprint, is bands that instead of being protected become enhanced in the presence of a bound protein. The likely explanation is that the protein induces some kind of structural alteration in the DNA, in a way that makes the DNA a better substrate for the DNaseI just outside the protected region.
DNaseI footprinting has also been used in more quantitative approaches to analyze protein–DNA interactions. Protocols for DNaseI footprinting can be found in specific reports, in several reviews, or in practically-oriented book chapters. Several agents have been used to generate supplementary methods of protection footprinting. Some of the common agents used are listed in Figure 4. Most of these are cleavage agents able to make incisions in DNA under mild conditions compatible with protein–DNA complex formation. In contrast, many of the agents used to modify DNA in interference methods cannot be used under such conditions.

2.2.3 Footprinting Using Dimethyl Sulfate

One very useful chemical agent is dimethyl sulfate (DMS) ((CH₃)₂SO₄). The use of DMS for DNA footprinting came after the development of methods for chemical DNA sequencing by Maxam and Gilbert. DMS is a strong methylating agent that will alkylate DNA in unprotected guanine bases in the N-7 position of the purine ring under mild conditions. The N-7 position is exposed in the major groove and is often involved in direct protein–DNA hydrogen bonding contacts in specific complexes. DMS also attacks, to a lower extent, adenine residues at N-3 positions exposed in the minor groove, but this has been less exploited for footprinting. Protein bound in the major groove will therefore protect guanine residues from methylation in the N-7 position. DNA fragments with this type of modification can be selectively cleaved by treatment with hot piperidine. Since DMS is a rather small chemical agent, it will be able to penetrate many regions where DNaseI is excluded, and thus provide a footprint of higher resolution. DMS is exceptional in that it may be used both in protection and interference types of footprinting. It will therefore be treated further in the section below.

DMS also has the ability to penetrate cells and modify DNA in chromatin. This has been the basis for development of methods for in vivo footprinting allowing the analysis of protein binding sites in a living cell. The first version of in vivo footprinting using DMS was presented by Church and Gilbert. They used DMS treatment of whole cells, DNA isolation followed by restriction digest, piperidine cleavage followed by electrophoretic separation and blotting of the sequencing gel and finally indirect end-labeling by hybridization to visualize the footprint. The introduction of ligation-mediated PCR was an important improvement to increase signal strength. The basic principle in this version is that DNA is isolated from DMS-treated cells, cleaved at the modified positions by piperidine, denatured and annealed to a target-specific oligonucleotide. After a fill-in reaction, the generated blunt end is then ligated to a common linker oligonucleotide. This generates fragments of different sizes with known sequences at both ends, and thus amenable to PCR amplification. The PCR amplification is performed using one target-specific primer and one primer complementary to the linker. The generated series of fragments will have one common end (the target-specific primer) and one end corresponding to the modified site that is cleaved, similar to what is the case in classical footprinting methods. To transform it into a series of radioactively labeled fragments, the technique ends with annealing a labeled primer that is extended to the end of the fragments. In parallel, a deproteinized preparation of genomic DNA is processed similarly. By comparing the two patterns obtained with chromatin versus naked template, the protective presence of proteins in the analyzed region can be demonstrated.

Several further developments of these principles have been reported. In particular, the analysis of genomic DNA in permeabilized cells or isolated nuclei by similar strategies expands largely the types of modifying agents that can be used. Genomic and in vivo footprinting have been treated in several reviews.

2.2.4 Exonuclease Footprinting

Probably the simplest version of protection footprinting methods is exonuclease footprinting. A complex is formed between an end-labeled DNA fragment and a specific protein, and the complex is treated with an exonuclease that digests the DNA in a directional fashion until it is hindered by the bound protein. The type of labeling must match the type of exonuclease used. A 5'-labeled DNA is suitable for 3'–5' types of exonucleases (like exonuclease III), while a 3'-labeled DNA can be treated with 5'–3' types of exonucleases (like the λ-exonuclease). The information provided by this type of footprinting is limited since only the borders of a protein–DNA complex
are mapped. On the other hand, it has the advantage of generating a positive signal in that the complex border is evidenced by formation of a novel specific band. In its simplest version, only one band is formed and a gel with lower resolution may be used to determine the size of the signal and thus to map the border of the complex.

The principle of exonuclease footprinting is illustrated in Figure 5.

Protocols for exonuclease footprinting can be found in specific reports, and in several reviews.

### 2.2.5 Hydroxyl Radical Footprinting

The smallest reactive agent used in protection footprinting is the hydroxyl radical, OH•. This highly reactive molecule is comparable in size to water and will penetrate many parts of the complex and attack DNA at most regions that are not in tight contact with the protein. No sequence preference is operating. This provides a footprint of high resolution with a lot of detailed information. The hydroxyl radical is generated by the Fenton reaction (Equation 5):

\[
\text{Fe}^{2+} + \text{H}_2\text{O}_2 = \text{Fe}^{3+} + \text{OH}^- + \text{OH}• \tag{5}
\]

Fe²⁺ is complexed with EDTA under these conditions and will not associate with DNA due to the negative charge of the complex. The hydroxyl radicals formed will attack the deoxyribose moieties and lead to chain cleavage. No separate cleavage step is therefore required. This method often does not produce totally clear zones in the footprint and it is an advantage to be able to scan the autoradiograms to quantify the footprint. It is a technically challenging footprinting method in particular because of the highly reactive agent involved. In some cases problems may arise because the hydroxyl radical attacks and inactivates the protein. The short lifetime of the reactive radical also demands rapid ways of mixing the hydroxyl radical-producing reagents with the protein–DNA complex. One should take care not to use protein solutions containing glycerol, since this is a radical scavenger and inhibits cleavage when present at concentrations higher than 0.5%.

Protocols for hydroxyl radical footprinting can be found in several reviews, or in practically-oriented book chapters.

### 2.2.6 Footprinting by other Chemical Cleavage Agents

Other chemical cleavage reagents used in footprinting methods include methidium–propyl–EDTA–Fe(II) (MPE-Fe(II)) which becomes associated with DNA by intercalation through its methidium group and thus acts more locally than hydroxyl radicals generated by the Fenton reaction. MPE-Fe(II) will, in the presence of ferrous ions, DTT, dioxygen and other reducing agents, efficiently cleave DNA. It cleaves the DNA backbone by an oxidative degradation of the deoxyribose ring, most likely by hydroxyl radicals. One advantage is the low sequence specificity producing a near-random cleavage pattern. This footprinting method was originally developed to map location of the binding sites for small protein–DNA complexes from a crude nuclear extract.

A related chemical DNA cleavage agent used for footprinting is 1,10-phenanthroline–copper. In its cuprous form, the coordination complex with hydrogen peroxide as a coreactant cleaves DNA by oxidatively attacking the deoxyribose moiety. An interesting practical application of this version is the direct footprinting of protein–DNA complexes embedded within the acrylamide matrix of an EMSA gel. This chemical agent associates with DNA in the minor groove where it leads to oxidative attack on the deoxyribose followed by strand cleavage. Protocols for these versions of footprinting can be found in specific reports, or in practically-oriented book chapters.

### 2.2.7 Footprinting of Structural Alterations in DNA

Binding of a protein to DNA may induce structural alterations including strand separations as occur in transcription and replication complexes. Such alterations can be probed by different footprinting agents that modify DNA in a structure-dependent fashion. Examples are KMnO₄ and OsO₄ which have a strong preference for single-stranded pyrimidines. Similarly, diethylylpyrocarbonate (DEPC) carbethoxylates purines at the N-7 position with a strong preference for single-stranded loops and also for purine residues in Z-DNA which appear structurally more accessible than in B-DNA.
2.2.8 Interference Footprinting Methods

Interference footprinting involves pretreatment of a duplex oligonucleotide or DNA fragment with agents that modify the DNA. The modified DNA is then used as a binding probe for a specific DNA-binding protein. The different methods vary with respect to the type of modification agent used. Their common feature is that they provide information on how DNA modification reactions in the binding site affect sequence-specific protein binding. The general principle of interference footprinting is illustrated in Figure 6.

An end-labeled duplex oligonucleotide or DNA fragment is here first treated by a modification agent under conditions that introduces "single hit" modifications randomly distributed along the sequence of DNA. This pretreated DNA is then allowed to bind to a specific DNA-binding protein under conditions that in an EMSA analysis would have given a reasonable amount of both complex and free probe (that is nonsaturating conditions). Then the complex is separated from noncomplexed DNA using an EMSA gel or using nitrocellulose filter binding. Both fractions of DNA (bound and nonbound) are isolated (eluted from the EMSA gel or from the filter) and subjected to cleavage by a reagent that cleaves specifically at the modified residues. A control of pretreated DNA without the protein is processed in parallel. When the generated fragments of DNA are then separated on a sequencing gel, the pattern of labeled bands will reveal at which positions the presence of a modified residue has interfered with protein binding. Fragments corresponding to these critical positions will be under-represented in the bound fraction, over-represented in the nonbound fraction, and have a normal intensity in the control fraction (note that the simplified version shown in Figure 6 only shows the bound and the control fraction). From this information, the location of the bound protein can be deduced.

2.2.8.1 Interference Footprinting by Dimethyl Sulfate

Probably the most common version of interference footprinting is analysis of DMS interference.\textsuperscript{36,37,70,101 – 103} As mentioned above, the alkylating agent DMS efficiently methylates N-7 of guanine bases, and thereby destroys critical contact points used for hydrogen bonding in many protein–DNA complexes. This type of interference footprinting therefore reveals guanine bases where interaction with N7 is of critical importance for sequence-specific DNA binding, as illustrated in Figure 7.

2.2.8.2 Missing Base Interference Footprinting

While DMS interference is limited to analysis of guanine bases (in the major groove), missing base interference footprinting is an informative version of interference footprinting that may provide data on the importance of all four bases in a binding site.\textsuperscript{104} Different chemical treatments generate either single-hit depurinated DNA (by treatment with formiate pH 2) or depyrimidated DNA.

![Figure 6](image_url)

**Figure 6** Schematic representation of the principle of interference footprinting methods.

![Figure 7](image_url)

DNA (by treatment with hydrazine). In these cases the entire bases are removed, and the argument is that if their presence is important for specific interactions with the protein, their absence will abolish or reduce binding. The cleavage reaction specific for the apurinic/apyrimidinic site is treatment with a solution of hot piperidine. Protocols for missing base interference analysis can be found in Ording et al.\(^{54}\) and Hørring et al.\(^{105}\)

**2.2.8.3 Missing Nucleoside Interference Footprinting**

This footprinting method is related to hydroxyl radical protection footprinting, but is performed as an interference version. This means that the end-labeled DNA is pretreated with hydroxyl radicals as described above. This modification leads to destruction of the base and sugar attacked (nucleoside) creating randomly distributed one-residue gaps in the strands of the duplex. This modified DNA can then be used as a probe according to a standard interference strategy. One advantage is that all nucleotides in a binding site can be probed. However, the gaps introduced may possibly alter the flexibility or conformation of the DNA, which may affect protein–DNA interactions.\(^ {106–108}\)

**2.2.8.4 Ethylation Interference Footprinting**

While most modification reagents attack either the bases or the sugar moieties in DNA, one reagent also attacks the phosphate groups and thus allows the analysis of critical phosphate interactions in the protein–DNA complex. This reagent is N-ethyl, N-nitroso-urea (ENU). ENU is an alkylating agent that will ethylate phosphate groups in DNA in a random fashion. This modification will interfere with protein binding at critical positions both due to the removal of a negative charge on the alkylated phosphate and because it introduces a bulky group that may interfere with binding for steric reasons. The modification specific cleavage reaction is performed under alkaline conditions.\(^ {103,109–111}\)

**2.2.8.5 Uracil Interference Footprinting**

Interactions between hydrophobic side chains and the 5-methyl group in thymine have been observed in many protein–DNA complexes.\(^ {14}\) A method has been devised to specifically analyze the importance of these interactions.\(^ {112}\) The thymine bases are randomly replaced with uracil (lacking the 5-methyl group) using a PCR reaction in the presence of TTP and dUTP that create “single hit” frequencies of substitutions. This modified PCR product is then used as a probe for binding according to the general interference strategy. The uracil-specific cleavage action requires after separation of bound and nonbound DNA is performed in two steps: first enzymatically using uracil-N-glycosylase that creates an apyrimidinic site, then chemically with piperidine. In this way it is possible to identify at which positions the removal of a 5’-methyl group in thymines will affect the binding of sequence-specific protein.\(^ {112–114}\)

**2.2.9 Summary**

The different versions of protection and interference footprinting methods described in this review exploit the modification of different parts of the DNA duplex, either specific bases or backbone components. For a summary, these various points of attack are illustrated in Figure 8.

Proteolytic mapping is a technique used to verify the primary structure of a protein. It involves the cleavage of the protein at specific amino acids to generate a unique set of peptides which is then separated and analyzed. The chromatogram generated during the separation is known as the proteolytic map of the protein, which serves as a unique “fingerprint” for that protein. A proteolytic map can be used to verify the identity of a protein and to detect mutations in a protein. This technique is faster than two-dimensional (2D) nuclear magnetic resonance (NMR), X-ray crystallography, or complete amino acid sequencing for verifying the primary structure of a protein. However, it does not allow determination of the sequence of a protein de novo as can be accomplished with sequencing, nor does it yield the higher order structural information that may be obtained with 2D NMR or X-ray crystallography.

The process of proteolytic mapping involves sample preparation, enzyme digestion, and map development. Each of these steps should be optimized for each new protein to obtain a good map; alternatively, generic protocols can be used to produce satisfactory results for some proteins. A typical protocol requires about a day to complete owing to the time required to digest a protein with an enzyme. However, more recent automated techniques are capable of completing the process in a few hours because they employ a highly concentrated immobilized enzyme which speeds digestion. Proteolytic maps are used in both quality control (QC) and research environments, with the most recent application in the field of proteomics.

1 INTRODUCTION

1.1 Description of Proteolytic Mapping

Proteins are polymers of amino acids that have a defined amino acid sequence and a specific three-dimensional structure when properly folded. Protein structure is classified into four levels. The sequence of the amino acids is the primary structure of a protein. Short lengths of amino acids can form helices, sheets or turns which are defined as the secondary structure of the protein. These elements fold together to define the overall three-dimensional structure of the protein which is known as the tertiary structure. Finally, some proteins combine with other proteins or additional copies of the same protein to form a complex (e.g. hemoglobin is composed of two α- and two β-chains) which defines a quaternary structure.
However, not all proteins have a quaternary structure. It is the primary structure (amino acid sequence) which defines the higher order structure (how the protein folds), and it is the three-dimensional structure of the protein which defines the function and activity of the protein.

During the synthesis of a protein, or afterwards, amino acids may be modified; for example, by phosphorylation, addition of carbohydrate, fatty acid acylation, reduction, oxidation, and proteolytic cleavage. These modifications are known as post-translational modifications (PTMs) and can be very important to the activity and proper function of a protein. Many techniques are available to probe the structure of a protein including X-ray crystallography, 2D NMR, SDS/PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis), isoelectric focusing, mass spectrometry (MS), circular dichroism, activity assays, Western blots, immunoaffinity techniques, and proteolytic maps. The focus of this chapter will be on proteolytic mapping and how it is used to verify the primary structure of a protein. The first step involves specifically cutting the protein into small peptides with either endoproteases (e.g., trypsin) or chemical cleavage (cyanogen bromide, CNBr). Cleavage is only performed at specified amino acids so the fragments generated are not random. The peptides are then separated, usually by chromatography, to generate a map that is specific to that protein. Changes in the amino acid sequence or in the PTMs will result in changes in the map. There are a number of excellent reviews discussing analysis by the proteolytic map technique.\textsuperscript{1–3}

### 1.2 Purpose and Uses of Proteolytic Mapping

Proteolytic mapping is typically used to verify the primary structure of a protein, although it can also be a useful tool in determining disulfide linkages and ascertaining tertiary structure. It is primarily the PTMs and amino acid substitutions which can be found by proteolytic mapping. Current peptide mapping techniques are sensitive enough to detect these modifications even when they are only present at a level of about 5% of the total protein product.\textsuperscript{4–6}

The peptide map alone is only sufficient to determine that there is a change in structure in relation to a known standard. Proteolytic mapping can also be used to identify an unknown protein (provided the sequence is in a database) by analyzing the peptide fragments by MS. With the list of masses of the peptide fragments and known conditions for digestion (e.g., tryptic digestion at only arginine and lysine residues) one may search the databases of known proteins to determine if the masses in the list match a theoretical digest of a protein in the database. This technique is used in proteomics to identify proteins from 2D gels.

### 1.3 History of Proteolytic Mapping

The basic protocols for proteolytic mapping are based on work from the 1960s by Crestfield et al.\textsuperscript{7} and Cleland\textsuperscript{8} that has since been developed to the point of its current use in QC.\textsuperscript{9–11} Initially, proteolytic digests were analyzed by thin-layer chromatography or SDS/PAGE. These map development techniques have since been replaced by high-performance liquid chromatography (HPLC) (see Figure 1 for an example peptide map); however, the digestion protocols have changed little. Although immobilized enzymes have been used for a long time,\textsuperscript{12,13} they have only gained acceptance for proteolytic mapping since more robust immobilized-enzyme cartridges have become available.\textsuperscript{14–19} These cartridges are based on a hydrophilic-coated polystyrene with wide pores (2000–4000 Å in diameter). The polystyrene base provides a pH-stable rigid support while the hydrophilic coating minimizes interactions with the proteins and peptides. Using these immobilized-enzyme cartridges, it has been possible to automate the entire process from reduction and alkylation, through digestion, peptide separation, and peak identification by MS.\textsuperscript{14}

### 1.4 Limitations

Again, the peptide map alone is only sufficient either to confirm the identity of a protein by comparison with a previous map of the same protein or to determine if there is a change relative to a previous map. The map in itself does not identify the nature of the change (amino acid mutation or different PTM). MS or peptide sequence analysis may be used to identify the peaks in the map. The combination of liquid

![Figure 1 Example proteolytic map of equine heart cytochrome c digested with trypsin and developed on a reversed-phase HPLC system monitoring absorbance at 215 nm.](image-url)
PROTEOLYTIC MAPPING

chromatography with MS in peptide mapping is a very powerful tool for protein structure elucidation and protein identification.

2 SAMPLE PREPARATION

2.1 Solubility Requirements

2.1.1 Reagents to Aid Solubility and Denaturation

Prior to proteolytic digestion, it is generally desirable to reduce the disulfide linkages between cysteine residues within the protein to assure complete digestion. To prevent disulfide reformation during later stages of the process, the sulfhydryl groups are blocked by alkylation. During the reduction process, proteins will often unfold and become insoluble in standard aqueous buffers. Also, the reduction will proceed more quickly if the protein is purposely denatured. Furthermore, the general chemistry of proteolytic digestion is most easily accomplished if the protein is soluble. For these reasons, chaotropic denaturants (e.g. 8-M urea [CAS 57-13-6] or 6-M guanidine hydrochloride [CAS 50-01-1]) are generally added prior to reduction in order to aid in the unfolding and solubilization of the protein. When using urea, it is important to prepare the solution fresh from dry stock in order to avoid carbamoylation from the cyanates which form upon storage of a urea solution. However, the cyanates may be removed from a stock solution by passing the solution through a bed of charged anion-exchange beads (e.g. Dowex™ beads) or placing the beads in the stock solution. Although detergents also aid in solubilization and denaturation of proteins, interference with either the digestion of the protein or in the analysis of the peptides in later steps of the proteolytic mapping can occur. If detergents are used, they may be removed by ion-exchange chromatography, but currently most protocols favor the use of chaotropes.

2.1.2 Digestion of Precipitated Proteins

When digesting a protein in a solution-phase format, endoproteinases will still digest a precipitated protein, and the liberated peptides will often be soluble. Generally, the digest will require longer incubation times than if the protein remained in solution. The chemical cleavage reagents also tend to work on precipitated protein but may require longer reaction times. However, if an immobilized proteolytic enzyme is to be used, steps must be taken to resuspend the protein for injection on to a column containing the immobilized protease.

2.2 Reduction

2.2.1 Purpose

Tightly folded proteins are difficult to digest. Denaturants are used to unfold a protein partially, but they have no effect on the covalent disulfide bonds that cross-link many proteins. Since these disulfide linkages between cysteine residues are quite effective in protecting a protein against denaturation, it is important to reduce these bonds to get an effective and complete digestion. Reduction is not required for proteins lacking internal disulfide linkages. Also, in the case of disulfide linkage assignment, it is desirable to digest the protein as much as possible without reducing these linkages.

2.2.2 Chemistry of Reduction

Typically, disulfide bonds are broken by adding excess reducing agents such as dithiothreitol (DTT) or mercaptoethanol [CAS 60-24-2] under neutral to alkaline conditions. However, phosphine reagents such as tris(2-carboxyethyl)phosphine (TCEP; CAS 51805-45-9) can also be employed under acidic conditions. During the reduction process one proton is added to each sulfur, hence, two reducing equivalents are required to reduce one disulfide bond. Although two molecules of mercaptoethanol will be required to reduce a disulfide bond, note that a single molecule of DTT (CAS 27656-41-9) is capable of completely reducing a disulfide bond since it carries two reducing equivalents.

2.2.3 Reagents

A very common reducing agent used for peptide mapping is DTT. It performs best under slightly alkaline conditions (pH 8) and more quickly if the protein is denatured and an elevated temperature is employed. Mercaptoethanol is more commonly used as a reducing agent for proteins prior to SDS/PAGE, but it can also be employed in peptide mapping. TCEP is being used with increasing frequency since phosphine reagents are effective even under acidic conditions.

2.2.4 Typical Protocol

1. Dissolve 2 mg of protein in 1 mL of freshly prepared 50-mM TRIS (tris(hydroxymethyl)aminomethane; CAS 77-86-1), pH 8.0 with 8-M urea.
2. Add 100 µL of 50-mM DTT to bring the concentration to about 4.5 mM.
3. Heat the solution at 50 °C for 20 min.
4. Cool to room temperature prior to alkylation.
2.2.5 Troubleshooting

A number of problems can occur during reduction. If the protein is highly disulfide-linked, more DTT may be required to reduce all the bonds. The conditions above assume that the protein contains one disulfide bond for each 3000 Da of mass (i.e. cysteine content of about 6%). If the number of disulfides is unknown and reduction seems to be incomplete, double the concentration of DTT in the reaction. If the cysteine content is at or below 6% and reduction is incomplete, increase the temperature for reduction (up to 90 °C). Upon reduction, many proteins will precipitate, illustrating the importance of the chaotrope not only to aid in denaturation but also aid in solubility. In some cases 6-M guanadine or SDS (sodium dodecyl sulfate) may be a good alternative to urea.

2.3 Alkylation

2.3.1 Purpose

Upon exposure to normal atmosphere, a solution of reduced protein will tend to reoxidize slowly. Oxidation can lead to reformation of disulfide linkages (often biologically incorrect linkages) or conversion to cysteic (SO₃) or cystein sulfenic (SO₂) acid. Alkylation is often performed to quench the reduced cysteines to prevent these oxidation events (see Figure 2 for diagram of reduction and alkylation process). Common alkylation reagents include iodoacetic acid (IAA; CAS 64-69-7), (IAM; CAS 144-48-9), and 4-vinylpyridine (4VP; CAS 100-43-6).

2.3.2 Chemistry of Alkylation

Alkylation is most often done immediately after reduction. An excess of alkylating reagent is required in order to ensure a complete reaction. Usually a molar excess of 10% over the reducing agent is used. Note that 1 mol of alkylating reagent is only equivalent to 0.5 mol of DTT since DTT will reduce a disulfide bond that generates two free cysteine residues. The alkylation reaction is very rapid and usually occurs in minutes; however, note that with the iodo alkylating reagents the reaction should be carried out in the dark or in amber vials in order to reduce the possibility of activating the iodine liberated in the reaction which will then modify tyrosine residues (light can generate an iodine free radical).

Also note that alkylation can be performed prior to reduction of a protein to derivatize any free cysteine residues that may be present in the protein. For example, if a protein contains an odd number of cysteine residues, there will be at least one that is not disulfide linked. The protein may be alkylated first with 4VP, then the remaining cysteine residues may be reduced and alkylated with IAM. In this way, the free cysteine may be identified since it will be the only cysteine alkylated with 4VP.

2.3.3 Reagents

Alkylation with IAA will add a negative charge to each cysteine. This charge may be desirable to avoid aggregation; however, the peptides digested from the protein will be more polar and, therefore, less retained on a reversed-phase column. If the peptide is too polar, it will not be retained. Also, when using IAA for alkylation, it is important to neutralize the reagent prior to use to avoid altering the pH of the reaction. Some vendors sell the sodium salt hence no neutralization is necessary. Alkylation with IAM results in a neutral side chain, less polar than that from IAA, and does not require neutralization prior to derivatization. Both IAM and IAA preferentially react with free cysteine residues, but will react more slowly with primary amines. It is important not to use an overwhelming excess of the reagent or allow the reaction to proceed too long since over-alkylation may result. The alkylation reaction may be quenched by addition of cysteine or thiomalic acid.

4VP has become popular because it will impart a positive charge for each cysteine. The extra charge helps

![Figure 2](image-url) Diagram of the reduction and alkylation of a protein with DTT and iodoacetamide (IAM), respectively.
improve ionization efficiency and therefore the detection of cysteine containing peptides by MS becomes more feasible. Vinylpyridine also has an absorption maxima at 254 nm and can be used for detection of cysteine-containing peptides spectrophotometrically. The ratio of the absorbance at 254 nm versus 280 nm is quite useful for this determination.\(^{26}\)

Acrylamide (CAS 79-06-1) can also be used to alkylate cysteine residues but is generally not used purposely in peptide mapping. Acrylamide adduction of cysteine residues sometimes occurs during polyacrylamide gel electrophoresis and is specifically mentioned since many proteins are purified for analysis on gels.

### 2.3.4 Typical Protocol

1. Using the reduced protein from the previous section, add 110 \(\mu\)L of 100-mM IAM.
2. Allow to react in the dark for 5 min at room temperature.
3. Dialyze overnight in the dark against 50-mM TRIS, pH 8, containing 10-mM CaCl\(_2\) (trypsin digest buffer).

### 2.3.5 Troubleshooting

The degree of alkylation can be checked by analyzing the protein before and after alkylation by MS. The mass should increase stoichiometrically with the number of expected cysteine residues. If the protein is under-alkylated either allow more time for alkylation or increase the amount of alkylation reagent. If the protein is over-alkylated (lysine residues can be alkylated), reduce the alkylation reagent concentration or time for the reaction. Proteins will often precipitate during alkylation, especially when using IAM that results in a neutral side chain. Precipitation is not always a serious problem since solution-phase enzymatic digestions will still digest precipitates. However, if an immobilized enzyme will be used, it is best to keep the protein soluble by adding urea to a concentration of about 6–8 molar.

### 3 PROTEOLYTIC DIGESTION

#### 3.1 Chemistry of Digestion

There are two general methods for fragmenting proteins for peptide mapping. Enzymatic digestion is most often employed using endoproteases which specifically recognize certain amino acids. The proteases catalyze the hydrolysis of the peptide bond on either the amino or carboxy side of a specific amino acid. The alternative is a specific chemical cleavage like CNBr (CAS 506-68-3) which will only cleave at methionine residues under the proper conditions.

#### 3.2 Selection of Enzyme or Reagent

Although trypsin is the most common enzyme used in proteolytic mapping, it is not always the best choice. Generally, the sequence of the protein of interest is known and by scanning the sequence for known proteolytic sites, an enzyme can be chosen which will generate appropriately sized fragments (see Table 1 for list of enzymes used for proteolytic mapping). The appropriate size is determined by the technique used to analyze the digest (usually reversed-phase HPLC). The purpose of digesting the protein is to generate smaller fragments so that small subtle changes to the overall protein constitute a larger and more significant change in a peptide fragment (e.g. deamidation leads to a 1-Da increase in mass which would be difficult to detect in an intact protein but much easier to detect in a peptide of just a few amino acids).

In some cases, more than one enzyme may be used either to generate two separate maps or in series to generate smaller fragments.\(^{27}\) It is also possible to use CNBr in combination with one of the proteases.\(^{28–30}\)

### 3.2.1 Trypsin

Since trypsin (EC 3.4.21.4) is the most widely used protease for proteolytic mapping, it will be discussed in the greatest detail. Trypsin is a serine protease which is very closely related to chymotrypsin (EC 3.4.21.1) and elastase (EC 3.4.21.36). Trypsin catalyzes the hydrolysis of peptide bonds on the carboxyl side of lysine and arginine residues, while chymotrypsin cleaves peptides on the carboxyl side of the bulky hydrophobic residues: tryptophan, tyrosine, and phenylalanine. Elastase, which is rarely used for proteolytic mapping, cleaves on the carboxyl side of small amino acids such as glycine and

</table>
alanine. The serine proteases are known as such because they contain a critical serine residue in their catalytic cleft that participates in stabilizing the transition state in hydrolysis. The specificity of the enzymes is determined by the size, shape, and charge in the catalytic cleft. Trypsin has a relatively deep, negatively charged cleft, accounting for its preference for positively charged amino acids, while chymotrypsin has a deep hydrophobic cleft and elastase has a shallow cleft accounting for their specificities. Trypsin has difficulty cleaving peptide bonds at lysine and arginine residues followed by an acidic amino acid such as glutamate or aspartate and does not cleave the bond at all if the next amino acid is a proline.

Cleavage of a protein with trypsin typically forms peptides on the order of 3–10 residues in length. With the exception of the C-terminal peptide, all of the tryptic fragments are guaranteed to contain at least one basic residue making analysis by positive ion MS much easier. However, trypsin is not the best enzyme for every protein. If there are too many cleavage sites (too many lysine and arginine residues) the resulting fragments may be too small and too numerous to generate a good peptide map. If there are too few cleavage sites then only a few large peptide fragments will be generated making detection of modifications more difficult.

Trypsin requires a calcium ion in order to maintain its most active structure; however, calcium is not absolutely required in the digestion buffer. On the other hand, chelators such as ethylene diamine tetraacetic acid (EDTA; CAS 60-00-4) will inhibit digestion because it essentially strips calcium from the enzyme. Trypsin, as well as the other serine proteases are also irreversibly inhibited by phenylmethyl sulfonyl fluoride (PMSF; CAS 329-8-98-6) which covalently attaches to the active site serine. PMSF and EDTA are common reagents used during cell lysis for the purpose of inhibiting proteolytic digestion and it is important that they be removed from the preparation prior to proteolytic mapping. Trypsin has an optimum activity at about pH 8 and its activity increases with temperature up to about 60 °C. However, most digestion protocols call for 37 °C since other side reactions can occur at elevated temperature. Trypsin also remains active in the presence of low concentrations of denaturants and organic solvents. The stability of trypsin can be improved by immobilizing it and by alkylating its lysine residues.

Trypsin is also autocatalytic, digesting itself as well as its substrate proteins. However, in the case of standard solution-phase digests, only small amounts of trypsin are added relative to the substrate protein (typically a ratio of 1:50 enzyme:substrate) to prevent the autohydrolytic fragments from trypsin from significantly interfering with the analysis of the protein of interest. Reductive methylation with formaldehyde and sodium borohydride decreases the autohydrolysis. Trypsin preparations often contain chymotrypsic activity as well, hence they are treated with N-tosyl-L-phenylalanlylchloromethyl ketone (TPCK; CAS 402-71-1) which specifically and irreversibly inactivates chymotrypsin. Almost all proteolytic mapping protocols call for TPCK-treated trypsin which is available from many vendors.

Since trypsin is relatively stable and has a neutral to basic pH optimum, it may be stored in 6-mM hydrochloric acid (HCl; CAS 7647-01-0) with minimal loss of activity over several days with refrigeration. Aliquots may also be frozen. HCl is chosen as the storage buffer since it has little buffering capacity. Thus, the HCl will have negligible effect on the pH of the digest solution upon its addition to a protein which is prepared in a buffered solution. Usually, the trypsin will be added at a ratio of 1:50 compared to the protein to be digested; hence, its overall volume contribution will also be negligible.

3.2.2 Chymotrypsin

Like trypsin, chymotrypsin (EC 3.4.21.1) is a serine protease and as mentioned earlier cleaves on the carboxyl side of the bulky hydrophobic residues: tryptophan, tyrosine, and phenylalanine. The optimum conditions for activity are pH 8 with activity increasing with temperature to about 60 °C, although most digestions are performed at 37 °C. Preparations of chymotrypsin are often contaminated with trypsin; hence, they are treated with N-tosyl-L-lysylchloromethyl ketone (TLCK; CAS 4238-41-9) to irreversibly inactivate the trypsin activity. TLCK-treated chymotrypsin is commercially available for peptide mapping applications. Chymotrypsin is chosen for proteolytic mapping only on rare occasions, but is nonetheless useful in special circumstances. Enzymes such as trypsin, Lys-C (EC 3.4.21.50), Arg-C (EC 3.4.22.8), Asp-N (EC 3.4.24.33), and Glu-C (EC 3.4.21.19) all insure that most of the peptides generated contain a charged amino acid: hence analysis by MS is straightforward. Since chymotrypsin cleaves at bulky hydrophobic residues, no such assurance is given. However, sometimes proteins contain many charged residues, thus cleavage with the other proteases leads to too many small peptides in the proteolytic map, leaving chymotrypsin as a better choice for sequence coverage.

3.2.3 Lys-C

Lys-C (EC 3.4.21.50), from Lysobacter enzymogenes, cleaves on the carboxyl side of lysine residues (thus its name). The optimum activity is at pH 8 and digestions are generally done at 37 °C. This protease is generally chosen when the digest fragments that are generated by trypsin are too numerous or too small because it cleaves...
at only one amino acid, lysine, instead of two amino acids, lysine and arginine. This enzyme is favored by mass spectrometrists because it guarantees the presence of at least one basic amino acid on every fragment except the C-terminal and generates relatively large fragments (typically twice as large as tryptic fragments).

### 3.2.4 Asp-N

Asp-N (EC 3.4.24.33), from *Pseudomonas fragi*, cleaves on the amino side of aspartic acid residues thus assuring that each proteolytic fragment, except the N-terminal, contains at least one acidic residue. It is not often used for proteolytic mapping but has specificity complementary to the more commonly used proteases. The optimum activity is at pH 8 and digestions are performed at 37 °C.

### 3.2.5 Glu-C

Glu-C (EC 3.4.21.19), from *Staphylococcus aureus*, also known as V8 protease, cleaves on the carboxyl side of glutamic acid (thus its name Glu-C) in pH 4 ammonium acetate buffer. Glu-C will also cleave on the carboxyl side of aspartic acid residues in pH 7.8 phosphate buffer. Note that under either set of conditions at least one acidic residue is guaranteed on each fragment except the C-terminal fragment.

### 3.2.6 Arg-C

Clostripain or Arg-C (EC 3.4.22.8), which cleaves on the carboxyl side of arginine residues (hence its name), may be obtained from *Clostridium histolyticum*. Arg-C can also be obtained from the mouse submaxillary gland (EC 3.4.21.40). Similar to Lys-C, the optimum activity is at pH 8 and digestions are generally done at 37 °C. Again, like Lys-C, this protease is generally chosen when the digest fragments generated by trypsin are too numerous or too small since it cleaves at only one amino acid, arginine, instead of two amino acids, arginine and lysine. This enzyme is also favored by mass spectrometrists because it guarantees the presence of at least one basic amino acid on every fragment except the C-terminal and generates relatively large fragments (typically twice as large as tryptic fragments).

### 3.2.7 Other Proteases Including Pepsin and Papain

Other proteases may be used for proteolytic mapping including pepsin, which has optimal activity under acidic conditions. This feature of pepsin is sometimes used when performing deuterium-exchange experiments. Once the deuterium exchange is complete, the protein is kept cold and at low pH to inhibit re-exchange. Pepsin and papain are also both used in the preparation of antibody fragments. Many of the new therapeutic proteins are either antibodies or based on antibodies. In performing a peptide mapping experiment on an antibody, it is sometimes useful to digest it first into the Fc and either two Fab fragments (pepsin) or one (Fab')2 fragment (papain) which are separated from one another prior to an additional digestion with another enzyme.

### 3.2.8 Cyanogen Bromide

CNBr cleaves proteins at methionine residues. Since methionine is a relatively rare amino acid, CNBr tends to generate very large fragments. Caution must be used when working with this reagent since cyanide gas can be liberated. Generally fume hoods are utilized and reactions are performed in sealed vessels. Upon cleavage, the product peptide will be terminated with either a homoserine or homoserine lactone moiety. Especially when analyzing digests by MS, it is important to identify both potential products.

### 3.3 Typical Protocol for Trypsin

1. Dissolve 1 mg of trypsin in 1 mL of 6-mM HCl (this may be frozen in aliquots for use up to 6 months later).
2. Remove the solution in the previous section which was dialyzed against 50-mM TRIS, pH 8.0 containing 10-mM CaCl₂ from the dialysis apparatus and transfer it to a polypropylene test tube. Trypsin will often digest precipitated protein.
3. Add 20 µL of the trypsin solution.
4. Incubate at 37 °C for 2 h.
5. Add another 20 µL of trypsin and incubate at 37 °C overnight.
6. Quench the reaction the next morning by adding 50 µL of trifluoroacetic acid (TFA; CAS 76-05-1).

### 3.4 Troubleshooting

The best way to check for completeness of a tryptic digest is by MS. If the digest is not complete, consider adding more enzyme (1:25) and/or allowing more time for digestion (up to 24 h). If MS reveals the presence of peptides with inappropriate cleavage sites (i.e. cleavage at chymotryptic sites) consider using less enzyme, decreasing digestion time, or finding a new source for the enzyme. Verify that the trypsin was treated with TPCK. Occasionally, peptides will precipitate upon cleavage from the intact protein. Often these peptides can be resolubilized with the addition of up to 5% TFA. Avoid the addition of organic solvents if possible, since
the next step is often reversed-phase chromatography in which organic solvent is used to elute the peptides from the column.

4 MAP DEVELOPMENT

Although there are a number of ways to separate and identify the peptides generated in a digest, the most common method for developing the peptide map after a digestion is reversed-phase chromatography with UV (ultraviolet) detection at around 210–230 nm. Older techniques included 2D thin-layer chromatography followed by detection with ninhydrin (CAS 485-47-2). Of course, the digest may also be analyzed directly by MS without any chromatographic separation (e.g. this is often the case with proteins digested from SDS/PAGE gel slices). A diagram for a typical chromatographic system for peptide mapping is shown in Figure 3.

4.1 Column Selection

The most common reversed-phase column for peptide mapping is the silica-based C_{18} column. The notation “C_{18}” refers to the length of the carbon chain covalently attached to the surface of the silica. Other reversed-phase columns of this classification include C_{4} and C_{8} columns which are less hydrophobic than the C_{18}, and therefore allow elution of hydrophobic peptides with much less organic solvent. There are also polystyrene-based reversed-phase columns that have a hydrophobicity similar to a C_{8} column, but they are difficult to compare directly with the silica-based columns because the mechanism of adsorption is slightly different, and therefore the elution order may also be different. Although resolution is sometimes poorer on a polystyrene column compared with the C_{18} columns, the polystyrene columns may be operated under basic conditions (the silica-based support will start to dissolve in alkaline media), thus allowing more flexibility in method development.

The appropriate column for developing the map depends upon the size, charge, hydrophobicity, and number of peptides generated. Typically, the C_{18} column is the best first choice. However, if it is known that the peptides generated from the digest are large and hydrophobic (e.g. CNBr digest), it may be better to use a less hydrophobic column such as the C_{4} or C_{8} columns. If for some reason alkaline reversed-phase conditions yield a better separation of the peptides than the typical acidic conditions, then a polystyrene column may be a better choice because it will withstand alkaline conditions much better than the silica-based columns. Unfortunately, there is no good way to select the best column a priori, so a number of columns and mobile phase conditions must be evaluated to determine which are appropriate for a particular digest.

Figure 3 Diagram of a chromatographic system for developing peptide maps.
4.2 Mobile Phase Selection

4.2.1 Solvents

Reversed-phase HPLC peptide maps are developed with a gradient from aqueous to organic solvent. Typical organic solvents for peptide mapping include acetonitrile (CAS 75-05-8), methanol (CAS 67-56-1), propanol (CAS 71-23-8), isopropanol (CAS 67-63-0), and ethanol (CAS 64-17-5), with the most popular reversed-phase solvent for peptide mapping being acetonitrile. Again, there is no good way of predicting the best solvent, but method developers usually begin with acetonitrile and only move to the other solvents if acetonitrile does not provide acceptable results. In addition to resolution, other factors to consider in the selection of a solvent include viscosity (higher viscosity will increase back pressure), UV cutoff (detector compatibility in general), disposal, and safety.

4.2.2 Mobile Phase Modifiers

The mobile phase modifier (e.g. TFA, HFBA [heptafluorobutyric acid; CAS 375-22-4], HCl, ammonium bicarbonate [CAS 1066-33-7]) usually serves more than one purpose. Not all of the surface silanol groups are covalently modified with a carbon chain in silica-based columns. Under neutral to basic conditions these silanol groups will be deprotonated leaving a negative charge on the surface which will interact with positive charges on peptides in the sample. Since these interactions will diminish resolution, they are suppressed by adding acids to the mobile phase to insure protonation and thus neutralization of the silanol groups.

Some of the modifiers are also known as ion-pairing agents. For example, TFA will interact with the positively charged residues on a peptide. Because TFA is hydrophobic, peptides that ion pair with it will be more retained on a reversed-phase column. Likewise, HFBA is even more hydrophobic than TFA and will cause these same peptides to be even more highly retained. A cationic ion-pairing agent, like tert-butylamine (CAS 75-64-9), will pair with negatively charged residues on the peptide thus causing the acidic peptides to be more highly retained. However, since this agent is used under basic conditions, it may be wise to consider the use of a polymeric column.

4.3 Gradient Optimization

Finding the right gradient for the best resolution in a minimum analysis time is one of the most challenging tasks in developing a proteolytic mapping protocol. In general, if there are large gaps in the peptide map, one tries to increase the slope of the gradient in these areas to save analysis time. In regions of overlapping peaks, the slope of the gradient is decreased to provide better separation even to the extent that an isocratic (no gradient) step is used. If the analysis will only be run occasionally, it may not be worth the investment in effort to reduce the analysis time. In fact, there are many cases in which a one- or two-hour gradient is used as a matter of routine with no further optimization.

4.4 Reproducibility

Reproducibility is measured in both retention time and peak area. Hoff and Pickering propose that the reproducibility of retention times of peaks in a peptide map have a standard deviation of less than 0.05 min in order to generate useful data. Many, but not all, HPLC systems are capable of delivering this performance. The performance capability of the HPLC system is also dependent on the column used to develop the map. Smaller columns (2.1 and 1.0 mm diameter) are more challenging since they operate at lower flow rates. Map reproducibility can also be greatly influenced by experimental technique. It is important to prepare the solvents precisely, and that they are degassed and filtered. Column temperature is another critical factor. Resolution can be improved with elevated temperature, but to attain reproducibility, it is important to keep a constant temperature from analysis to analysis. Typically, a column oven is used to maintain the temperature at 37°C. Of course, sample injection must also be precise and accurate, and the injection valve should have less than 0.1% carryover between injections. Sample handling is another important consideration and is somewhat protein dependent. It is generally a good idea to refrigerate a stored digest taking care to avoid oxidation, evaporation (change concentration), or contamination.

4.5 Typical Protocol

1. Select a 4.6-mm-internal diameter × 250-mm-length C18 reversed-phase column.
2. Prepare 0.1% TFA in water for solvent A and 0.08% TFA in acetonitrile as solvent B filtering through a 0.2-µm solvent compatible filter (like nylon).
3. Set the detector wavelength to 214 nm.
4. Set up the column and solvents on an HPLC and program a method that will equilibrate the column for 15 min at 1 mL min\(^{-1}\) with 100% solvent A, then inject 50 µL of a 1 mg mL\(^{-1}\) digest, and run a linear gradient to 30% solvent A + 70% solvent B in 60 min. At the end of the gradient, wash the column for 10 min in 100% solvent B. The entire method should be run at 1 mL min\(^{-1}\).
5 IDENTIFICATION OF PEPTIDE PEAKS

Although the peaks in the map can be used as a fingerprint to identify a protein compared to a control, it is often desirable or necessary to determine the identity of the peptides in each of the peaks. This is especially true when a new unexpected peak is found. There are a number of ways to identify the peaks, but currently the most popular and most definitive techniques are peptide sequence analysis and MS.

5.1 Retention Time Prediction

Retention times of peptides can be estimated based on the sequence. Although these models are very good, they are not perfect and reality often deviates from the theoretical. If two peptides are very similar (e.g. same sequence except for one residue) prediction is very successful, but in the case of proteolytic mapping it is best to use these models only as a guide.

Another route to retention time prediction is to generate all of the peptides expected in a map synthetically and then analyze them individually to determine their retention time. Although this may seem like the most difficult way to accomplish the task, it can have some advantages. It can be especially useful to find the retention time of expected contaminants or breakdown products. For example, if one is concerned whether an active site cysteine is oxidized, a fragment may be synthesized with the cysteine oxidized and analyze it on the column. When a complete digest is analyzed and that peak does not appear one can say that cysteine oxidation at that site was not observed. Essentially, this technique may be used to guide the researcher in his interpretation of the chromatogram for potential problems.

5.2 Ultraviolet Spectral Analysis

Although most peptides have a similar UV spectra, they are not identical (they especially depend upon the aromatic amino acid content). Further, derivatization (e.g. alkylation with vinylypyridine) may create unique spectral signatures which can be identified. For example, if vinylypyridine is used for alkylation, cysteine-containing peptides may be identified by determining the ratio of the absorbance at 254 nm and 280 nm. However, not all peptides can be uniquely identified this way. The purity of peaks in the peptide map may also be checked by a UV spectral analysis. If a peak contains only one pure peptide, the spectrum at the beginning, middle and end of the peak should remain constant, except for intensity. Any change in the spectrum throughout the peak will indicate that a second peptide or impurity is present.

5.3 Amino Acid Analysis

Amino acid analysis involves the hydrolysis of the peptide fragment into its component amino acids. This gives a composition of the peptide, not the sequence. Unfortunately, asparagine and glutamine are converted to aspartate and glutamate, respectively, and tryptophan is degraded. However, it is still often possible to deduce the sequence from the composition when the sequence of the intact protein is known. Also, amino acid analysis is a quantitative determination giving the amount of peptide present. It is also possible to find modified amino acids with this technique. For example, the amino terminal residue can be located by specifically labeling it with fluorodinitrobenzene.

5.4 Peptide Sequence Analysis

To determine the sequence of a peptide or protein, N-terminal sequence analysis by Edman degradation has been the dominant technique for many years. However, there are now viable competing techniques which include C-terminal sequence analysis and MS.

5.4.1 N-terminal

Edman degradation involves the systematic removal of one amino acid at a time from the amino terminus of the peptide or protein. First, phenyl isothiocyanate (CAS 103-72-0) is used to derivatize the neutral amino terminal of the peptide under alkaline conditions. Then, by changing the buffer conditions to a slightly acidic environment, a cyclic derivative is formed with the terminal amino acid as it cleaves from the peptide which is then ready for another cleavage cycle. Since the peptide or protein is immobilized on a resin or membrane, reagent addition, buffer change, and analysis of the liberated amino acid by HPLC are easily automated. Unfortunately, this method of sequence analysis is not useful if the amino terminal end of the protein or peptide is blocked.

5.4.2 C-terminal

The C-terminal sequence analysis process proceeds much the same way as N-terminal sequence analysis except by different chemistry so that a single amino acid is removed from the carboxyl terminus. The peptide or protein is first attached to a Zitex™ membrane, then coupled with diphenyl phosphoroisothiocyanatidate (DPPITC). The coupled, membrane-bound peptide is washed with acetonitrile to remove excess DPPITC and then treated with pyridine to effect ring closure, anhydrous TFA, and finally trimethylsilanolate to cleave a single thiohydantoin-amino acid which is identified by retention on a reversed-phase column. The shortened
peptide is then cycled through the process again to determine the next amino acid.\cite{36}

**5.5 Mass Spectrometry**

MS is rapidly becoming the dominant technique for protein and peptide characterization. This is partly because of a decrease in price for performance (i.e. lower-priced MS systems are improving in sensitivity and resolution). There are a variety of mass spectrometers available, but they are generally classified by the type of ionization employed (e.g. electrospray ionization (ESI) and MALDI (matrix-assisted laser desorption ionization) are most popular for proteins and peptides) and the type of mass analyzer used (e.g. time-of-flight [TOF], quadrupole [Q], or ion trap). Because most ionization sources can be fitted to almost any mass analyzer, many combinations are possible. Further, mass analyzers may be coupled in tandem mass spectrometry (known as MS/MS) first to select an ion based upon its intact mass, fragment the ion, and then analyze its fragments on a second mass analyzer. Although many MS/MS systems use the same type of mass analyzer for both steps, it is not a requirement as is the case for ESI/Q/TOF. Some combinations are more logical than others, hence, not every conceivable product is available. As technology improves, the combinations which appear to be logical are subject to change.

There are also a number of options available for coupling a reversed-phase column used to develop the map of a mass spectrometer. The most direct way is though an electrospray source which will ionize the peptides in the flow stream as they elute from the column and desolvate them prior to introduction into the high vacuum of the mass analyzer. However, fractions may also be collected from the reversed-phase column and then injected into an electrospray source or applied to a MALDI target with the matrix. Application of fractions to a MALDI target have been automated using either robots or a specialized fraction collector which will apply the fractions directly to the plate as they elute. In this case, matrix is applied in a second pass.

**5.5.1 Peptide Intact Mass**

The simple molecular mass of a peptide from a protein of a known sequence digested with a known enzyme is often more than sufficient to assign the identity of a peptide unambiguously. Of course, the probability that this is true improves as the accuracy of the measurement improves. Also, given several peptide masses from a protein digested with a specific enzyme, even an unknown protein may be uniquely identified from a database given sufficient mass accuracy.\cite{37}

**5.5.2 Sequence Analysis with Enzymes (Carboxyl and Amino Peptidases)**

Peptides can be sequenced by MS utilizing either amino or carboxypeptidases to digest from one end of the peptide, one amino acid at a time. The objective is to generate a series of peptides which differ by only one amino acid in length, in effect generating a “ladder” from which the sequence may be read by determining the difference in mass between each peak in the ladder. The difficulty with this technique is that the enzymes used for this purpose often do not cleave all amino acids at equal rates, hence, there may be gaps or stops in the ladder sequence. Unfortunately, this technique cannot distinguish between the isomers leucine and isoleucine (lysine and glutamine can also be difficult to distinguish because they differ by only 0.04 Da).

**5.5.3 Sequence Analysis by Mass Spectrometry**

When peptides are ionized in a gas phase, they can be fragmented in a number of ways. In fact, if the ionization method is harsh they may spontaneously fragment. Peptides can fragment at three points along the peptide bond: between the carbon and nitrogen that make the peptide bond, between the nitrogen and \(\alpha\)-carbon, or between the \(\alpha\)-carbon and carbonyl. Also upon fragmentation of a singly charged peptide, only one fragment or the other receives the charge. The neutral species will not be detected. With three potential fragmentation points multiplied by the two possible directions in which the charge may transfer, there are six possible fragments that can be generated known as \(a\), \(b\), \(c\), \(x\), \(y\), and \(z\) (see Figure 4 for fragmentation examples). Unfortunately, this is only the simplest case. It is also possible to fragment within the amino acid side chains, and it is possible to generate internal fragments (i.e. two bonds broken and the charge carried by the middle fragment). Often, a great deal of expertise is required to interpret an MS/MS spectrum.

**5.5.3.1 Tandem Mass Spectrometry**

The most common way to cause fragmentation once the peptide is in the mass spectrometer is by introduction of a collision gas (collision-induced dissociation [CID]). In many MS/MS experiments, an initial mass analyzer is tuned to the mass of interest allowing only that ion to continue to the area where fragmentation occurs. Then, the fragments which retain the charge are separated on the second mass analyzer. A good example of this technique is demonstrated with a triple Q instrument in which one Q is used for the initial mass separation, a second for fragmentation, and a third to analyze the fragments. The major advantage of MS/MS is that relatively complex mixtures may be infused, and a single species may be selected for further
fragmentation and MS analysis. This is not the case with in-source fragmentation and post-source decay where relatively pure peptides are required in order to interpret the fragmentation patterns.

5.5.3.2 In-source Fragmentation Fragmentation of peptides can also be achieved in the source of a mass spectrometer. In this experiment, only one mass analyzer is used to analyze the fragments, but the major limitation is that only one component can be infused into the instrument at a time or else data interpretation becomes extremely complicated with fragments from multiple peptides.

5.5.3.3 Post-source Decay Post-source decay applies peptides that fragment after initial acceleration in a MALDI TOF MS. Fragmentation can also occur prior to acceleration but the ionized fragments from such a decomposition would be found in the original spectrum. Post-source decay allows for detection of fragments generated post acceleration due to fission of bonds along the peptide backbone. To separate and detect these fragments in a TOF instrument, an ion mirror (reflector) that will cause the ionized fragments to reverse course must be used and the neutral fragments must be allowed to pass through undetected. The reflected peptide fragments are then detected using stepped-mirror voltages to reflect lower-mass fragments.

6 AUTOMATION OF PROTEOLYTIC MAPPING

The entire proteolytic mapping process including reduction and alkylation has been automated. A number of authors have shown various ways of accomplishing this depending on the goals of the mapping process. Central to these methods is an immobilized proteolytic enzyme that rapidly digests the substrate protein. For example, when trypsin is immobilized, its autolytic capability is greatly reduced due to its immobility. Therefore, high concentrations of trypsin can be used to speed the digestion considerably (normally the slowest step of proteolytic mapping, taking several hours to overnight to complete), so that it only takes a few minutes. Immobilization also improves the stability and lifetime of the enzyme so it can be used repeatedly.

Using column switching valves, a column packed with trypsin can be used first to digest an intact protein and pass the fragments on to an analytical column. Then, the enzyme column can be switched off-line while the analytical column is resolved (see Figure 5 for an example plumbing diagram). Further, the reduction and alkylation of the protein can be performed in some autosamplers allowing these modifications to be completed while the reversed-phase column equilibrates with the starting solvents. Given this type of automated system, it takes no longer to analyze an intact protein than one which had been prepared manually using an overnight digestion. Automation can make method development easier as well as lead to improved reproducibility, especially between operators.

6.1 Automating Reduction and Alkylation

Many autosamplers and robotic workstations are capable of automating the process of reduction and alkylation of a protein. To perform this process, the machine must be capable of adding reagents, heating the sample, and mixing the sample. Automation of these steps has a number of advantages including the fact that the protein is freshly prepared and less likely to be oxidized, carbamylated, or otherwise modified by storage for long periods of time in the alkylation reagents. Automation generally leads to better reproducibility, especially between operators, and finally automation allows around-the-clock operation.
6.2 On-line Digestion with Immobilized Enzymes

The use of immobilized enzymes for on-column digestion has long been reported. However, many problems with early attempts were due to the instability of the silica support at the basic pH used for tryptic digestions. Trypsin autohydrolytic fragments were the major problem encountered until a hydrophilic-coated polystyrene-based resin was used for enzyme immobilization. The base polystyrene is mechanically rigid under typical HPLC pressures and chemically inert over a wide pH range. The hydrophilic coating minimizes hydrophobic interactions with either the protein or its digest fragments. Immobilized enzymes are generally more stable than those in free solution. For example, immobilized trypsin can be used in either organic solvents (up to 50% acetonitrile) or at high temperature (up to 60 °C).

Immobilized enzyme columns are plumbed in tandem with an analytical reversed-phase column. Since the enzymes do not tolerate the harsh organic solvents used in reversed-phase, switching valves are used to take each of the columns in and out of line at the appropriate times. Also, the HPLC pumps must be capable of delivering at least three different solvents: digestion buffer, aqueous reversed-phase solvent, and organic reversed-phase solvent. A typical method includes flushing the system with reversed-phase solvents with both columns off-line followed by engaging the reversed-phase column and equilibrating it with the aqueous starting solvent. Then, the columns are switched out of the flow path again to allow the system to be flushed with digestion buffer after which the enzyme column is cleaned and equilibrated with digestion buffer. Then, the flow rate is slowed (about 10–50 µL min⁻¹), both columns are placed in-line, and a protein sample is injected. First, the sample slowly passes through the enzyme column, it is digested, and then it passes through the reversed-phase column which captures the peptide fragments. Once digestion and capture are complete, both columns are switched off-line to be flushed with reversed-phase solvents. Then, the reversed-phase column is engaged and eluted with a gradient of organic solvent as in standard proteolytic mapping (see Figure 6 for an example of reproducibility of an automated system).

6.3 Liquid Chromatography/Mass Spectrometry to Automate Peak Identification

As with a standard solution-phase digestion peptide mapping protocol, the automated protocol is easily coupled to MS. Coupling to electrospray is straightforward, but automated methods are also available to couple to MALDI.

6.3.1 Electrospray Ionization

Coupling to electrospray is quite simple. The outlet of the reversed-phase column is coupled directly to the mass spectrometer. However, there are some tips that will improve performance and sensitivity. First, the flow rate from the column may not be optimal for sensitivity on the mass spectrometer and a flow splitter may be needed. Also, the initial flow-through peak from the injection of the peptides often contains salts, buffers, and urea. It is best not to pass these substances through the spray tip of the mass spectrometer, even if the shutter is closed. It is better to use a diverter valve to send this fraction to waste. Finally, the ion-pairing agent used for optimum resolution on the reversed-phase column may not be optimal for sensitivity in the ionization source. For example, TFA sometimes interferes with sensitivity while ion-pairing agents like formic or acetic acid are more well behaved. Either a switch may take place to a more favorable ion-pairing agent or a make-up solvent may be added to the flow stream (also known as a TFA...
PEPTIDES AND PROTEINS

Figure 6 Example of the reproducibility of automated peptide mapping in each case starting with a fresh sample of native human serum albumin which is automatically reduced and alkylated, digested, and then analyzed by reversed-phase HPLC.

“fix”) to minimize the interference from the ion-pairing agent.

Direct coupling of the column to the mass spectrometer is perhaps most desirable since the mass data is collected in real time; but, this is not required. Fractions may be collected and then infused at a later time. This may be desirable if concentration of the fraction is necessary or if additional chemistry is to be performed prior to mass spectral analysis.

6.3.2 Matrix-assisted Laser Desorption Ionization

Although MALDI can be coupled directly to reversed-phase chromatography,\(^\text{(39)}\) it is often desirable simply to deposit fractions on to the MALDI target. This may be done by collecting fractions and manually or robotically redispensing fractions from the original tubes on to the MALDI target. Alternatively, the fractions may be applied to the target as they elute from the reversed-phase column using a modified fraction collector and flow splitter. A matrix must also be added to each sample to aid in desorption and ionization.

6.4 Database Searching to Identify Proteins

A reversed-phase peptide map provides a fingerprint of a protein that can be matched against the maps of other proteins in an attempt to identify it. The map is highly technique-, column-, and instrument-dependent so although the identity of a known protein can be confirmed, it is difficult to identify an unknown protein. However, if the masses of these proteolytic fragments are known, the observed masses can be compared with the expected theoretical masses generated from a digest of all proteins in a sequence database. It is not necessary to digest and analyze the database proteins, but simply to have a correct sequence from which a theoretical digest is generated. In addition to searching databases with a set of peptide masses known to originate from a single protein, databases may also be searched for specific peptide sequences. For example, if a peptide fragment from a protein is sequenced by Edman degradation, the database can be searched with that sequence to find the protein from which it came. Also, since MS/MS fragmentation contains sequence information, MS/MS data can be submitted for a database search to find peptides that would theoretically produce a similar fragmentation pattern.

7 SELECTED APPLICATIONS

There are a variety of applications for proteolytic mapping and the use of the data generated depends upon the application. For example, mapping is performed in the QC environment to confirm the identity of a protein by simply using its “fingerprint” from the HPLC chromatogram. All peaks are important, and any loss of peaks or any new peaks indicate problems. In contrast, in typical proteomics applications, one only wishes to identify a protein based on the masses of the observed fragments. Not all of the masses are needed to identify the protein. In addition, any extraneous masses may come from a variety of sources, may not indicate a problem, and can often be ignored.

7.1 Mapping in the Quality Control Environment

The most important feature of a proteolytic mapping procedure in the QC environment is robustness. The method must give consistent reproducible results over time and between operators. This has been one of the driving forces for automating the proteolytic mapping
process. Typically, 4.6-mm diameter columns are used for reversed-phase analysis since most HPLC pumping systems are able to deliver very reproducible gradients using a column of this size (typically operated at 1 mL min⁻¹). Owing to their large volume, these columns are not the most sensitive. However, because the sample is usually not limiting in the QC environment, the sample is sacrificed for robustness.

Considerable effort is placed on developing a method specific to the protein to be analyzed. To diminish variability, complete digestion is usually required with no partially digested fragments. Great care is taken to avoid additional modifications such as oxidation during the process which may obscure modifications incurred prior to proteolytic mapping. After all of the peaks in the HPLC chromatogram have been identified once (usually by sequence analysis and/or MS) they are not re-identified in the final routine assay. Chromatographic retention time is considered to be sufficient identification henceforward.

7.2 Miniaturization for Increased Sensitivity in Research and Development

The research and development (R&D) environment is quite different from the QC environment in that large amounts of sample are often difficult to obtain. For example, one may wish to identify contaminants in a product that are present at the 1% level. Since the sample identity is unknown, the mapping procedure will not be optimized for the sample. Consequently, a generic method employed for most proteins will be used. Further, complete information about the sample may not be required, and a simple identification may be sufficient. If only identification is needed, the chromatographic separation may be circumvented and the digest may be analyzed directly by MS since only a few fragment masses will be required to identify uniquely the protein.

However, if further characterization is required (i.e. the contaminant may be a product that is oxidized and verification is needed), chromatographic separation may be necessary prior to MS in order to allow each of the peptides to ionize more efficiently. When analyzing a mixture by MS, quenching of some analytes by others is often observed (analytes which ionize easily obscure those that ionize less readily). A chromatographic separation allows the peptides to be presented individually to the mass spectrometer to avoid this competition. Again, to attain the highest level of sensitivity, digestions are usually performed in solution in small volumes using microbore or capillary HPLC columns to develop the map. The robustness of a larger column is sacrificed for the sensitivity of a capillary column.

7.3 Application to Proteomics

Generally, in a proteomic application, the goal of proteolytic mapping is to identify the protein based upon its mass fingerprint, hence a reversed-phase separation of the peptide fragments is rarely used. Instead, the digest is analyzed directly by MS. Also, unlike mapping in the QC and R&D environment, relatively large amounts of trypsin (or other proteolytic enzyme) may be used. The enzyme autohydrolysis peptides which interfere in the other analyses may be used as internal calibration standards in proteomic applications. The peptide masses are then submitted to a database searching program that looks for proteins that would give the same masses if digested with the same enzyme as used in the experiment. Results of the search are improved by using more peptides and by having good mass accuracy.

1 INTRODUCTION

RPHPLC is now the central chromatographic technique in the analysis, structure elucidation and isolation of peptides and proteins and has therefore played a critical role in the enormous advances made in the biological sciences over the last 20 years. The extraordinary success of RPHPLC can be attributed to a number of factors. These include (1) the excellent resolution that can be achieved under a wide range of chromatographic conditions for very closely related molecules in addition to structurally distinct molecules, (2) the experimental ease with which chromatographic selectivity can be manipulated through changes in mobile phase characteristics, (3) the generally high recoveries and hence high productivity and (4) the excellent reproducibility of repetitive separations carried out over a long period of time, which is due partly to the stability of the sorbent materials under a wide range of mobile phase conditions. However, RPHPLC can cause the irreversible denaturation of protein samples, thereby reducing the potential recovery of material in a biologically active form.

The RPHPLC experimental system for the analysis of peptides and proteins usually consists of an n-alkylsilica-based sorbent from which the solutes are eluted with gradients of increasing concentrations of organic solvent such as acetonitrile containing an ionic modifier such as trifluoroacetic acid (TFA). Complex mixtures of peptides and proteins can be routinely separated and low picomolar–femtomolar amounts of material can be collected for further characterization. Separations can be easily manipulated by changing the gradient slope, the operating temperature, the ionic modifier or the organic solvent composition.

The extensive use of RPHPLC for the purification of peptides, small polypeptides with molecular masses up to 10 000 Da and related compounds of pharmaceutical interest has not been replicated to the same extent for larger polypeptides (molecular mass > 10 000 Da) and globular proteins. The combination of the traditionally used acidic buffering systems and the hydrophobicity of the n-alkylsilica supports which can result in low mass yields or the loss of biological activity of larger polypeptides and proteins have often discouraged practitioners from using RPHPLC methods for large-scale protein separations. The loss of enzymatic activity, the formation of multiple peaks for compositionally pure samples and poor

yields of protein can all be attributed to the denaturation of protein solutes during the separation process using RPHPLC.(3–6) Whilst these features detract from the use of RPHPLC as a technique of choice in preparative purification protocols with proteins, these same characteristics can provide a unique opportunity to study protein folding and stability. Thus, the widespread practical application of RPHPLC has been recently accompanied by a significant improvement in our understanding of the molecular basis of the retention process and its impact on conformational stability of both peptides and proteins. As a result, RPHPLC can now also be used as a physicochemical tool for the analysis of the dynamic behavior of peptides and proteins at hydrophobic surfaces.(7–15)

The challenge facing the scientist who wishes to analyze and/or purify a peptide or protein sample is the selection of the initial separation conditions and subsequent optimization of the appropriate experimental parameters. This article provides an overview of the different experimental options available to achieve a high-resolution separation of a peptide or protein mixture using RPHPLC. The interested reader is also referred to a number of recent publications which provide a comprehensive theoretical and practical overview of RPHPLC of peptides and proteins together with other modes of high-performance chromatography.(16–20)

2 NATURE AND ORIGIN OF SAMPLES

RPHPLC is extremely versatile for the isolation of peptides and proteins from a wide variety of synthetic or biological sources and is used for both analytical and preparative applications.(1,2) Analytical applications

Conditions: linear gradient from 0 to 60% acetonitrile with 0.1% TFA over 30 min, flow rate 1 mL min⁻¹, 25°C. (b) Semi-preparative profile (10 mg). Column: Brownlee RP-C18, 15 cm × 10 mm ID, 5 µm particle size, 30 nm pore size. Conditions: linear gradient from 0 to 60% acetonitrile with 0.1% TFA over 60 min, flow rate 1 mL min⁻¹, 25°C. (c) Analytical profile (1 mg) of purified peptide. Chromatographic conditions as in (a).
range from the assessment of the purity of peptides following solid-phase peptide synthesis (21) to the analysis of tryptic maps of proteins (22). Preparative RPHPLC is also used for applications from the micropurification of protein fragments for sequencing (23) to large-scale purification of synthetic peptides (21) and recombinant proteins (24).

The complexity of the mixture to be chromatographed will depend on the nature of the source and the degree of preliminary cleanup that can be performed. In the case of synthetic peptides, RPHPLC is generally employed for both the initial analysis and the final large-scale purification. The purification of synthetic peptides usually involves an initial separation on an analytical scale to assess the complexity of the mixture followed by large-scale purification and collection of the target product. A sample of the purified material can then be subjected to RPHPLC analysis under the same or different elution conditions to check for purity. An example of this procedure is illustrated in Figure 1(a–c) for the purification of a synthetic pentapeptide.

The isolation of proteins from a biological cocktail derived from a tissue extract or biological fluid, for example, often requires a combination of techniques to produce a homogeneous sample. High-performance liquid chromatography (HPLC) techniques are then introduced at the later stages following initial precipitation, clarification and preliminary separations using soft gels. Purification protocols therefore need to be tailored to the specific target molecule and often involve the strategic combination of a range of high-performance techniques including ion-exchange, size-exclusion, hydrophobic interaction, reversed-phase and affinity chromatography methods. One example of the use of multidimensional separations is shown in Figure 2(a–c), where the judicious use of size-exclusion, ion-exchange and RPHPLC methods...
resulted in the efficient purification of mEGF(25) in which manipulation of the sample between stages has been minimized and selectivity has been maximized.

Peptide mapping by RPHPLC is now an indispensable tool in the characterization of new proteins and the quality control of proteins derived from recombinant DNA.(22)

An example of the high-resolution analysis of a tryptic digest of a protein is shown in Figure 3.(26) This figure, in which 150 protein fragments were resolved, demonstrates the highly selective separation that can be achieved with enzymatic digests of proteins using RPHPLC as part of the quality control or structure determination of a recombinant or natural protein. The chromatographic separation was obtained with an C2/C18 stationary phase packed in a column of dimensions 10 cm × 4.6 mm internal diameter (ID). Separated components can then be directly subjected to further analysis such as automated Edman sequencing or electrospray mass spectrometry (ESMS).

### 3 THE ROLE OF PEPTIDE AND PROTEIN STRUCTURE IN RETENTION

The mechanism by which peptides and proteins are retained in RPHPLC involves the hydrophobic expulsion of the solute from the polar mobile phase followed by adsorption on a nonpolar sorbent.(27) Peptides and proteins are thus retained to different extents depending on their surface hydrophobicity, the elutropicity of the mobile phase and the nature of the hydrophobic ligands. The physicochemical basis of RPHPLC lies in the hydrophobic interaction between a peptide or protein and the hydrophobic sorbent, and can be described in terms of the solvophobic theory where the isocratic retention factor can be expressed as Equation (1):(27)

\[
\ln k' = \log k_0 - N\Delta A_h + 4.836N^{1/2}(k_e^S - 1)\frac{V^2}{RT} \phi
\]  

(1)

where \(N\) is Avogadro’s number, \(\Delta A_h\) is the hydrophobic contact area of the interacting solute, \(V\) is the mean molar volume of the solvent, \(R\) is the gas constant, \(T\) is the temperature and \(\phi\) is the surface tension of the mobile phase. The parameter \(k_e^S\) is the ratio of the energy required to create a cavity for a solvent molecule and the energy required to extend the planar surface of the liquid by the surface area of the solute molecule. Thus, simply stated, elution in RPHPLC is achieved through a decrease in the microscopic surface tension associated with the solute–sorbent interface. Experimentally this is achieved through changes in the water content by variation in the mole fraction of organic solvent in RPHPLC. However, high-resolution isocratic elution of peptides and proteins can rarely be achieved as the experimental window of organic solvent concentration required for solute elution is typically very narrow. Hence peptides and proteins are generally separated using gradient elution conditions. Under these conditions, the experimentally observed retention data can be analyzed according to the linear solvent strength (LSS) model [Equation 2].

\[
\log K = \log k_0 - S\phi
\]  

(2)

where \(K\) is the solute median capacity factor and \(\phi\) is the corresponding organic mole fraction. The \(\log k_0\) value is the affinity of the solute for the sorbent in the absence of organic solvent. By analogy with the solvophobic Equation (1) above, the \(S\) value is related to the hydrophobic contact region established between the solute and the sorbent surface. Both \(S\) and \(\log k_0\) can be derived from plots of \(\log K\) versus \(\phi\) and the LSS model provides the computational basis for the rational optimization of peptide and protein separations. An example of these plots is shown in Figure 4 for a series of peptide analogs related to neuropeptide Y-[18–36] which differ in sequence only by the substitution of a single D-amino acid residue.(7) The data presented in these plots provide a clear example of how to optimize
RPHPLC IN PEPTIDE AND PROTEIN ANALYSIS

Figure 5 Chromatograms showing the separation of the all-L-NPY-[18–36] peptide and NPY-[18–36] analogs with D-substitutions at positions 19, 20, 23, 25 and 28 separated on a C_{18} silica [Bakerbond (J.T. Baker, Phillipsburg, NJ, USA) RP-C_{18}, 25 cm × 4.6 mm ID, 5 µm particle size, 30 nm pore size] with a 60-min gradient from 0 to 50% acetonitrile at 1 mL min^{-1}. The separation was used to derive the retention plots shown in Figure 4. (Reproduced from Lazoura et al. by permission of The Biophysical Society.)

separations, whereby maximum optimization will be achieved by selecting elution conditions where there is the greatest separation between the retention plots. The elution profiles of five of the NPY-[18–36] analogs are shown in Figure 5 and demonstrate that the order of elution of the peaks corresponds to the relative position of the retention plots shown in Figure 4 and also illustrates the corresponding degree of resolution that is obtained.

The plots shown in Figure 4 also illustrate the ability of RPHPLC to resolve very small differences in peptide structure as each NPY-[18–36] analog exhibited significant differences in α-helical structure in different solution environments. These and other studies thus serve to illustrate how RPHPLC can act as a molecular probe of peptide surface topography. In particular, analysis of the S and log k_0 values as a function of temperature can be used to gain significant insight into the conformational integrity of peptides and proteins during interaction with hydrophobic surfaces.

Peptides and proteins are retained in RPHPLC through hydrophobic interactions. As depicted in Figure 6(a), the hydrophobic contact region for small peptides involves the contribution from all or a large proportion of the peptide structure. As a consequence, the retention time for small peptides can be predicted on the basis of

the amino acid composition through summation of the hydrophobicity coefficients for the constituent amino acid residues. In contrast, it has been well established that proteins interact with the chromatographic surface in an orientation-specific manner, in which their retention time is determined by the molecular composition of specific contact regions. For larger polypeptides and proteins which adopt a significant degree of secondary and tertiary structure, there is no correlation between retention times and the summated hydrophobicity coefficients of all constituent amino acid residues. In these cases, the chromatographic contact region comprises a small proportion of the total molecular surface as shown in Figure 6(b) and (c). It is also generally observed that the retention time increases with increase in solute molecular mass as a result of increases in hydrophobic surface area. However, it is the molecular composition of the contact region that determines the retention and bandwidth properties of the peptide or protein solute. Thus, in the presence of any degree of preferred secondary structure,
no simple relationship will exist between the retention time and the summated retention coefficients unless the identity of the contact region can be established.

An example of the potential impact that protein conformational changes can have on the elution profiles in RPHPLC is shown in Figure 7. This figure shows the elution profiles of horse apocytochrome c chromatographed on a C<sub>18</sub> silica [Bakerbond (J.T. Baker, Phillipsburg, NJ, USA) RP-C<sub>18</sub>, 25 cm × 4.6 mm ID, 5 µm particle size, 30 nm pore size] over gradient times of 30, 45, 60, 90 and 120 min from 0 to 50% acetonitrile at 1 mL min<sup>-1</sup> at 5 °C. The first- and second-eluted conformers are denoted 1 and 2, respectively. (Reproduced from K.L. Richards, M.I. Aguilar, M.T.W. Hearn, ‘A Comparative Study of the Retention Behaviour and Stability of Cytochrome c in RPHPLC’, J. Chromatogr., 676, 17–31 (1994), Copyright 1994, by permission from Elsevier Science.)

4 OPTIMIZATION OF RESOLUTION
An appreciation of the experimental factors that control the resolution of peptides and proteins in interactive modes of chromatography is essential in the development and manipulation of separation protocols to obtain the desired separation. The optimization of high-resolution separations of peptides and proteins involves the separation of sample components through manipulation of both retention times and solute peak shape. In the following sections, the different RPHPLC techniques which are commonly employed for the analysis and purification of peptides and proteins are described. In particular, the experimental approaches that can be used to manipulate resolution in order to achieve a particular level of separation are discussed below in terms of the parameters that control resolution and are illustrated with relevant examples.

4.1 Stationary Phase
The most commonly employed experimental procedure for the RPHPLC analysis of peptides and proteins generally involves the use of an octadecylsilica-based sorbent and a mobile phase. The chromatographic packing materials that are generally used are based on microparticulate porous silica which allows the use of high linear flow velocities, resulting in favorable mass transfer properties and rapid analysis times.<sup>37–39</sup> The silica is chemically modified by a derivatized silane bearing an n-alkyl hydrophobic ligand. The most commonly used ligand is n-octadecyl (C<sub>18</sub>), while n-butyl (C<sub>4</sub>) and n-octyl (C<sub>8</sub>) also find important application and phenyl and cyanopropyl ligands can provide different selectivity.<sup>40</sup> The process of chemical immobilization of the silica surface results in approximately half of the surface silanol group being modified. The sorbents are therefore generally subjected to further silanization with a small reactive silane to produce an end-capped packing material.

The type of n-alkyl ligand significantly influences the retention of peptides and proteins and can therefore be used to manipulate the selectivity of peptide and protein separations. Although the detailed molecular basis of the effect of ligand structure is not fully understood, a number of factors including the relative hydrophobicity and ligand chain length, flexibility and the degree of exposure of surface silanols all play a role in the retention process.<sup>41–45</sup> An example of the effect of chain length on peptide separations is shown in Figure 8(a) and (b).<sup>11</sup> It can be seen that the peaks labelled T<sub>3</sub> and T<sub>13</sub> are fully resolved on the C<sub>4</sub> packing but cannot be separated on the C<sub>18</sub> material. In contrast, the peptides T<sub>5</sub> and T<sub>18</sub> are unresolved on the C<sub>4</sub> column but fully resolved on the C<sub>18</sub> material. In addition to effects on peptide selectivity, the choice of ligand type can also influence protein recovery and conformational integrity of protein samples. Generally higher protein recoveries are obtained with the shorter and less hydrophobic n-butyl ligands. However, proteins have also been obtained in high yield with n-octadecylsilica.<sup>46–48</sup>
The use of nonporous particles of smaller diameter. The geometry of the particle in terms of the particle size, 30 nm pore size; there are also examples of sorbents with varying surface hydrophobicity, and in which the surface silanol groups have been masked. The desired levels of efficiency and sample loading size required for their elution is very narrow. Mixtures of peptides and proteins are therefore routinely eluted by the application of a gradient of increasing organic solvent concentration.

4.2 Mobile Phase

One of the most powerful characteristics of RPHPLC is the ability to manipulate solute retention and resolution through changes in the composition of the mobile phase. In RPHPLC, peptide and protein retention is due to multisite interactions with the ligands. The practical consequence of this is that high-resolution isocratic elution of peptides and proteins can rarely be achieved as the experimental window of solvent concentration required for their elution is very narrow. Mixtures of peptides and proteins are therefore routinely eluted by the application of a gradient of increasing organic solvent concentration. RPHPLC is generally carried out with an acidic mobile phase, with TFA being the most commonly used additive owing to its volatility. Phosphoric acid, perchloric acid, formic acid, hydrochloric acid, acetic acid and heptafluorobutyric acid have also been used.

Alternative additives such as nonionic detergents can be used for the isolation of more hydrophobic proteins such as membrane proteins.

The three most commonly employed organic solvents in RPHPLC are acetonitrile, methanol and 2-propanol, which all exhibit high optical transparency at the detection wavelengths used for peptide and protein analysis. Acetonitrile provides the lowest viscosity solvent mixtures and 2-propanol is the strongest eluent. An example of the influence of organic solvent is shown in Figure 9, where changes in selectivity can be observed for a number of peptide peaks in the tryptic map. In addition to the eluotropic effects, the nature of the organic solvent can also influence the conformation of both peptides and proteins and will therefore have an additional effect on selectivity through changes in the structure of the hydrophobic contact region. In the case of proteins, this may also impact on the level of recovery of biologically active material.
small peptides and proteins, increased resolution will be obtained with increases in column length. Thus, for applications such as tryptic mapping, column lengths between 15 and 25 cm and ID of 4.6 mm are generally employed. However, for larger proteins, low mass recovery and loss of biological activity may result with these columns due to irreversible binding and/or denaturation. In these cases, shorter columns of between 2 and 20 cm in length can be used. For preparative applications on the 1–2 mg scale, such as the purification of synthetic peptides, so-called semipreparative columns of dimensions 30 × 1 cm ID and preparative columns of 30 × 2 cm ID can be used.

The selection of the ID of the column is based on the sample capacity and detection sensitivity. While most analytical applications are carried out with columns of 4.6 mm ID (as shown in Figures 3, 5 and 8), for samples derived from previously unknown proteins where there is a limited supply of material, the task is to maximize the detection sensitivity. In these cases, the use of narrowbore columns of 1–2 mm ID can be used, which allow the elution and recovery of samples in much smaller volumes of solvent. Capillary chromatography is also finding increasing application where capillary columns of 0.2–0.4 mm ID and a length of 15 cm result in the analysis of femtomole amounts of sample, as shown in Figure 10. The effect of decreasing column ID on detection sensitivity is shown in Figure 11 for the analysis of lysozyme on a C18 material packed into columns of 4.6, 2.1 and 0.3 mm ID.

### 4.4 Operating Parameters

There are several operating parameters that can be changed in order to manipulate the resolution of peptide and protein mixtures in RPHPLC. These parameters include the gradient time, the gradient shape, the mobile phase flow rate and the operating temperature. A typical experiment with an analytical-scale column would utilize a linear gradient from 5% to between 50 and 100% organic solvent over a time range of 20–120 min while flow rates are between 0.5 and 2.0 mL min⁻¹. With microbore columns (1–2 mm ID) flow rates of 50–250 µL min⁻¹ are used, while for capillary columns of 0.2–0.4 mm ID, flow rates of 1–4 µL min⁻¹ are applied.
Retention time (min)

Figure 11 Effect of column ID on detector sensitivity. Column: Brownlee RP-300 C8 (7 μm particle size, 30 nm pore size), 3 cm × 4.6 mm ID and 10 cm × 2.1 mm ID (Appl. Biosystems) and 5 cm × 0.32 mm ID. Conditions: linear gradient from 0 to 60% acetonitrile with 0.1% TFA over 60 min, 45 °C. Flow rates: 1 mL min⁻¹, 200 μL min⁻¹ and 4 μL min⁻¹ for the 4.6, 2.1 and 0.32 mm ID columns, respectively. Sample loadings: lysozyme, 10, 4 and 0.04 μg for the 4.6, 2.1 and 0.32 mm ID columns, respectively. (Reproduced from R.L. Moritz, R.J. Simpson, ‘Application of Capillary Reversed-phase High-performance Liquid Chromatography to High Sensitivity Protein Sequence Analysis’, J. Chromatogr. 599, 119–130 (1992), Copyright 1992, by permission from Elsevier Science.)

At the preparative end of the scale with columns of 10–20 mm ID, flow rates between 5 and 20 mL min⁻¹ are required.

The choice of gradient conditions will depend on the nature of the molecules of interest. The influence of gradient time on the separation of a series of ribosomal proteins is shown in Figure 12(a–c). Generally, the use of longer gradient times provides improved separation. However, these conditions also increase the residence time of the peptide or protein solute at the sorbent surface, which may then result in an increase in the degree of denaturation.

The operating temperature can also be used to manipulate resolution. While the separation of peptides and proteins is normally carried out at ambient temperature, solute retention in RPHPLC is influenced by temperature through changes in solvent viscosity. In addition, peptide and protein conformation can also be manipulated by temperature. Changes in temperature can therefore also be used to manipulate the structure and retention of peptide mixtures. For peptides, it has been shown that secondary structure can actually be enhanced through binding to the hydrophobic sorbent. In the case of proteins which are to be subjected to further chemical analysis and thus where recovery of a biologically active protein is not essential, increasing temperature can be used to modulate retention via denaturation of the protein structure. However, if the efficient recovery of both mass and biological activity is of paramount importance, the use of elevated temperatures is not an option.

The chromatographic recovery of proteins from polyacrylamide gels is another important application of RPHPLC. Inverse gradient elution chromatography has been successfully utilized for the micropreparative isolation of proteins from sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE) electroeluates. This approach is based on observations that certain RPHPLC packings display strong interactions with proteins at high organic solvent concentrations. This allows the loading of the electroeluate under conditions where the protein is retained while the sodium dodecyl sulfate and other gel-related contaminants are washed through the column. The protein is then recovered in high yield by a gradient of decreasing organic solvent.

Detection of peptides and proteins in RPHPLC, generally involves detection at between 210–220 nm which is specific for the peptide bond, or at 280 nm which corresponds to the aromatic amino acids tryptophan and tyrosine. The use of photodiode array detectors can enhance the detection capabilities by the on-line accumulation of complete solute spectra. The spectra can...
then be used to identify peaks specifically on the basis of spectral characteristics and for the assessment of peak purity. In addition, second derivative spectroscopy can provide information on the conformational integrity of proteins following elution.

5 MASS SPECTROMETRY DETECTION

One of the most significant recent advances in bioanalytical technology has been the advent of mass spectrometry for the analysis and measurement of peptide and protein molecular mass. In particular, the development of on-line ESMS following RPHPLC [liquid chromatography/electrospray mass spectrometry (LC/ESMS)] has provided a powerful detection system for the rapid analysis of peptides and proteins. For example, LC/ESMS significantly facilitates the identification of peptide fragments in peptide mapping studies, as illustrated in Figure 13(a) and (b), which shows the analysis of an Arg-C digest of plasminogen activator separated on a C18 column with (a) the total ion current and (b) the elution profile at 214 nm. Figure 14 shows the RPHPLC separation of a Lys-C specific endopeptidase (Lys-C) digest of two forms of apolipoprotein A1 in which there is a significant difference in the retention time of the last major peak K15. Subsequent on-line LC/ESMS revealed the presence of an arginine–cysteine substitution and illustrates the power of LC/ESMS in the analysis of microheterogeneous forms of naturally derived proteins or protein mutants with as little as one change in the amino acid sequence. Other important applications involve the identification of posttranslational modifications of peptides and proteins including sites of N- and O-linked glycosylation, and the identification of disulfide bonds and the identification

Chromatogr.*, **A717**, 41–60 (1995), Copyright 1995, by permission from Elsevier Science.)
of peptides bound to major histocompatibility complex molecules. Although LC/ESMS has clearly enhanced the analytical power of RPHPLC, the analysis of large complex proteins can be hindered by the wide range of peptides generated by enzymatic digestion, particularly in the case of heterogeneous glycoproteins. In these circumstances, multidimensional analytical techniques such as capillary electrophoresis and matrix-assisted laser desorption/ionization time-of-flight (MALDI/TOF) mass spectrometry can be used to complement the information obtained by LC/ESMS and further expand the analytical capability of RPHPLC techniques.

6 CONCLUSIONS AND FUTURE DIRECTIONS

RPHPLC is now an indispensable tool for the high-performance separation of complex mixtures of peptides and proteins. The number of applications of RPHPLC in peptide and protein purification continues to expand at an extremely rapid rate. Solid-phase peptide synthesis and recombinant DNA techniques have allowed the production of large quantities of peptides and proteins which need to be highly purified. The design of multidimensional purification schemes to achieve high levels of product purity highlight the power of RPHPLC techniques in the production of peptide- and protein-based therapeutics.

Consequently, RPHPLC is now firmly entrenched as the central tool for the analysis of peptides and proteins and, in particular, plays a pivotal role in the pharmaceutical industry, providing the core analytical technique at all stages of the development of peptide- and protein-based therapeutics. Following purification, mass spectrometry can be used to confirm the structural identity of synthetic peptides, while recombinant proteins require further structural analysis by high-resolution analytical
fingerprinting to confirm the amino acid sequence. RPHPLC will therefore continue to be the central method for the characterization and quality control analysis of synthetic peptides and recombinant proteins. Moreover, the coupling of mass spectrometry to allow on-line identification of samples will become routine and continue to expand the analytical power of HPLC.

Other areas of separation technology in which significant advances are expected to emerge are in the areas of miniaturization and high-speed analysis to allow the efficient purification of femtomolar to attomolar levels of material. These techniques will have an important impact on the discovery of new bioactive peptides and novel proteins as potential candidates for new therapeutics.

The development of fully mechanistic models which describe the underlying thermodynamic and kinetic processes involved in the interaction of peptides and proteins with hydrophobic stationary phase surfaces has not kept pace with the growth of RPHPLC applications. This is predominantly due to the complex nature of peptide and protein structure and difficulties in determining the precise structure of the solvated sorbent material. However, both spectroscopic and molecular modeling techniques are starting to provide detailed molecular information on peptide and protein surface interactions, which will not only allow further advances in the rational design of new sorbent materials but will further establish RPHPLC as a physicochemical tool for the analysis of peptide and protein surface interactions.

Finally, there has been a strong synergy between the biotechnology industry and the field of biomacromolecular RPHPLC as several significant recent advances in separation technology have been driven by the stringent and continually evolving regulatory requirements of the biotechnology industry. RPHPLC will therefore continue to be at the heart of the analytical techniques with which scientists in all areas of biomolecular research must arm themselves to be able to characterize fully the identity, purity and potency of peptides and proteins.

This chapter presents a detailed overview of the theoretical basis of surface plasmon resonance (SPR) spectroscopy, emphasizing both principles and practical considerations such as thin-film designs for SPR devices which can be employed in characterization of biological materials, including peptides and proteins. It is demonstrated that the analysis of the resonance spectrum yields structural parameters of anisotropic films of interacting biomolecules, including distribution of mass, long-range molecular order, and molecular conformational changes. Binding parameters, including binding affinities and rate constants, can also be determined. A summary is presented of different techniques for biomolecule immobilization on SPR-generating surfaces applicable in peptide and protein analysis.

1 INTRODUCTION

1.1 General Overview of the Surface Plasmon Resonance Spectroscopy Technique

The concept of surface plasmons (SPs) derives from the plasma formulation of Maxwell’s theory of electromagnetism, where the free electrons of a metal (or a conductive electron gas) are treated as a high-density liquid (plasma). Plasma oscillations in metals are collective longitudinal excitations of the conductive electron gas, and plasmons are the quanta representing these charge-density oscillations. When such oscillations occur on an interface between a metallic and a dielectric surface they are called SPs, or surface polaritons. These propagating electron-density fluctuations generate evanescent SP electromagnetic waves (or guided surface electromagnetic waves), which propagate along the plane metal/dielectric media interface, with the electric field normal to this interface. The concept of surface plasmons (SPs) derives from the plasma formulation of Maxwell’s theory of electromagnetism, where the free electrons of a metal (or a conductive electron gas) are treated as a high-density liquid (plasma). Plasma oscillations in metals are collective longitudinal excitations of the conductive electron gas, and plasmons are the quanta representing these charge-density oscillations. When such oscillations occur on an interface between a metallic and a dielectric surface they are called SPs, or surface polaritons. These propagating electron-density fluctuations generate evanescent SP electromagnetic waves (or guided surface electromagnetic waves), which propagate along the plane metal/dielectric media interface, with the electric field normal to this interface. It has been shown that Maxwell’s equations have solutions resulting in the generation of SP electromagnetic waves only when the frequency, \( w \), and wave vector, \( k \), meet special requirements which produce the following constraints:

1. one of the adjacent media (i.e. the surface-active medium which generates SP waves) has a negative value for the real part of its complex dielectric constant, \( \varepsilon \);

2. a component of the wave vector along the interface between these two media satisfies an equation which involves the dielectric constants of both media (see below).

The complex dielectric constant, \( \varepsilon \), is directly related to the complex index of refraction \( N = c/v = n - ik \), by Equation (1):

\[
\varepsilon = \varepsilon' + i\varepsilon'' = N^2
\]

where the real part of the complex dielectric constant is \( \varepsilon' = n^2 - k^2 \), and the imaginary part is \( \varepsilon'' = 2nk \), \( n \) is the refractive index, \( k \) is the extinction coefficient, and \( v \) is the velocity of light in the dielectric medium. In the optical region of the electromagnetic spectrum, the
complex index of refraction is numerically equivalent to the optical admittance, $Y$, which is defined by the ratio of the amplitudes of the electric and magnetic fields of the electromagnetic wave.\(^{(3)\!}\)

The condition that the surface-active medium has a negative dielectric constant results in several experimental requirements which have to be fulfilled in order to be able to generate SP waves. First of all, not all materials can be used as surface-active media; gold (Au), and silver (Ag) are the best examples of materials that can support SPs. In addition, the electromagnetic wave in the surface-active medium is an evanescent wave under all circumstances. Therefore, SPs can only be optically generated by an evanescent wave excited under total internal reflection conditions (obtained with either prisms or gratings), by a transverse magnetic (TM) component, $p$, of incident light of wavelength, $\lambda$ (or frequency, $\omega$), whose component wave vector parallel to the metal interface, $k_{ph}$, which is described by Equation (2):

$$k_{ph} = \frac{\omega}{c} \epsilon_0^{1/2} \sin \alpha$$ \hspace{1cm} (2)

matches that of the evanescent SP electromagnetic wave $k_{SP}$ (Equation 3):

$$k_{ph} = k_{SP}$$ \hspace{1cm} (3)

The latter is given by Equation (4):

$$k_{SP} = \frac{\omega}{c \left[ \epsilon_1 \epsilon_2 / (\epsilon_1 + \epsilon_2) \right]^{1/2}}$$ \hspace{1cm} (4)

where $\omega$ is the frequency of the SP wave (and excitation light wavelength), $c$ is the velocity of light in vacuo, and $\epsilon_1$ and $\epsilon_2$ are the complex dielectric constants for the surface active and dielectric (emerging) media, respectively.\(^{(2)\!}\)

At the resonance condition (Equation 3), the incident light is coupled into a plasmon wave travelling along and bound to the outer active (metal) surface, and the phenomenon is known as SPR.

As Equation (3), taken together with Equations (2) and (4), indicates, the resonance condition can be achieved by changing either the incident angle, $\alpha$, with constant value of plasmon excitation light frequency, $\omega$ (or wavelength, $\lambda$), or by changing $\omega$ (or $\lambda$) at a constant value of the incident light angle, $\alpha$. During the resonance interaction, energy is transferred from photons to plasmons, so that the effect of plasmon excitation can be observed as a sharp minimum of the reflectance when either angle of incidence is varied at the same light wavelength, or light wavelength is varied at the same incident angle, thus defining an SPR spectrum. In both instances this spectrum reflects the resonance in absorption of incident photons.\(^{(4)\!}\)

SPR can also be detected with a fluorescence technique known as total internal reflectance fluorescence (TIRF), employed with waveguided systems. The application of TIRF to monitor SPR is based on the following properties of the surface modes. First, there is a possibility that the nonradiative SP modes can, under specific conditions, decay into light, thereby allowing emission techniques to be used to detect the resonance.\(^{(5)\!}\) Nonradiative SPs can decay into photons of the same frequency if coupling by the surface roughness takes place. The intensity of emitted light images the SPR occurring at silver and gold surfaces, producing an emission resonance curve similar to that of the reflectance resonance curve obtained under attenuated total reflection (ATR) conditions. Second, the surface bound electric field generated by SP modes can be used as an efficient source to excite fluorescence emission of molecules adsorbed at the SPR active surface. This property of the plasmon electromagnetic field allows the monitoring of resonance by using fluorescent labeling of molecules adsorbed (or immobilized) on the active surface of the SPR-producing medium.

In practical terms there are two configurations, both based on the ATR technique, available to optically excite and to monitor SPR at the metal/dielectric (or emerging medium) interface. In the first, the Kretschmann configuration,\(^{(6)\!}\) the prism is in direct contact with the surface-active (metal) medium. In the second, the Otto configuration,\(^{(7)\!}\) the prism is separated by a thin layer of a dielectric (inactive) medium at a distance of approximately one wavelength of excitation light from the metal film.

There are three principal designs of resonators resulting in four different types of resonances:

(i) Conventional Surface Plasmon Resonance. This can be generated by a prism whose hypotenuse is coated with a single high-performance metal (Ag or Au) layer.\(^{(4,8–16)\!}\) Such a device produces a resonance that is characterized by a very large increase of electromagnetic field amplitude of the evanescent wave bound to the outer surface of the metal,\(^{(4)\!}\) compared with that of the incident wavelength. It has the characteristics of a sharp resonance and can only be obtained with $p$-polarized excitation light. Figure 1 compares the calculated resonances observed with reflected light intensity for both metals and both variables i.e. either as a function of $\alpha$ with $\lambda = \text{const}$ (panel a), or vs $\lambda$ at $\alpha = \text{const}$ (panel b).

(ii) Long-range Surface Plasmon Resonance. This is generated in the same way as conventional SPR, but with a thinner metal layer, which is surrounded by dielectric media that are beyond the critical angle so that they support evanescent waves.\(^{(3)\!}\) Figure 2 demonstrates an example of calculated LRSPR reflectance vs incident angle (panel a) and LRSPR reflectance as a function of light wavelength (panel b) spectra. As can be seen these
are much narrower resonances than conventional SPR (Figure 1), which indicates a much higher evanescent electromagnetic field intensity generated by LRSPR. Furthermore, LRSPR involves two surface-bound waves on both the inner and outer surfaces of the metal layer compared with one wave in the conventional resonance.

(iii) Coupled Plasmon-waveguide Resonance. This involves even more complex assemblies in which SPRs in a thin metal film are coupled with guided waves in a dielectric overcoating, resulting in excitation of both plasmon and waveguide resonances, a combination known as coupled plasmon-waveguide resonance (CPWR). A coupled plasmon-waveguide resonator contains a metallic layer (the same as in a conventional SPR assembly), which is deposited on either a prism or a grating and is overcoated with either a single dielectric layer or a system of dielectric layers, characterized by appropriate optical parameters so that the assembly is able to generate surface resonances upon excitation by both $p$- and $s$-polarized light components. As can be seen from Figure 3, the addition of such a dielectric layer (or layers) to a conventional SPR assembly plays several important roles. First, it functions as an optical amplifier which significantly increases electromagnetic field intensities at the dielectric surface in comparison to conventional SPR. This results in an increased sensitivity and spectral resolution (the latter due to decreased resonance linewidths). Second, it enhances spectroscopic capabilities (due to excitation of resonances with both $p$- and $s$-polarized light components), which results in the ability to directly measure anisotropies in refractive index and optical absorption coefficient in a thin film adsorbed onto the surface of the overcoating. Third, the dielectric overcoating also serves as a mechanical and chemical shield for the thin metal layer in practical applications.

(iv) Long-range Coupled Plasmon-waveguide Resonance. This is generated by a resonator which combines both the long-range SP and coupled plasmon-waveguide resonators into one device. The resulting resonance spectra are similar in shape and intensity to those obtained with CPWR devices.

1.2 Use of Coupled Plasmon-waveguide Resonators to Measure Anisotropic Properties of Thin Films

The standard mathematical tool used to describe the SPR phenomenon, as well as the optical properties of
multilayered thin-film devices such as the SPR resonators, can be seen as a straightforward result of the application of thin-film electromagnetic theory. In the case of SPR which is generated optically with the ATR technique, the reflectance, $R$, of a multilayer system, defined as the ratio of the energy reflected at the surface of such a structure to the energy which is incident, depends not only on the optical parameters of the sensing layer, but also on the optical parameters of both incident and emerging media as well as the metal film (or metal/dielectric layers in CPWR), generating the resonance. It can be calculated from Equations (5a, 5b, 5c):

$$ R = r r^* $$  \hspace{1cm} (5a)

where:

$$ r = \frac{Y_0 - Y}{Y_0 + Y} $$  \hspace{1cm} (5b)

is the amplitude reflection coefficient (reflectivity or Fresnel reflection coefficient), and:

$$ r^* = \left\{ \frac{Y_0 - Y}{Y_0 + Y} \right\}^* $$  \hspace{1cm} (5c)

is the complex conjugate of $r$. $Y$ is the optical admittance of a multilayer-thin-film assembly and can be calculated with the help of the characteristic matrix of such an assembly. $Y_0$ is the admittance of the incident medium (which in the case of the present application to SPR is a non-light-absorbing glass prism, i.e. with $k = 0$, and therefore the $Y_0$ value becomes real and equal to the refractive index of the incident medium, $n_0$). Equations (5a), (5b), and (5c) comprise a set of mathematical tools to examine optically excited SPR by analyzing the SPR spectrum represented by the reflectance, $R$, as a function of either the incident angle, $\alpha$, or the wavelength, $\lambda$. Such an analysis can be applied to all three types of resonance: SPR, LRSPR, and CPWR, and results in three optical parameters (refractive index, $n$, extinction coefficient, $k$, and thickness, $t$) which characterize the properties of a dielectric layer. These three optical parameters characterizing a deposited dielectric film (including protein, lipid, and lipid–protein layers) can be evaluated in the case of CPWR for both exciting light polarizations, at different angles of light incidence, and using different light wavelengths, thereby producing enough experimental data to characterize all of the structural parameters of thin films, i.e. thickness, orientation of molecules (by measuring the anisotropy in $n$), and the orientation of chromophores attached to the molecules within the sensing layer (by measuring the anisotropy.
SURFACE PLASMON RESONANCE SPECTROSCOPY IN PEPTIDE AND PROTEIN ANALYSIS

Figure 3 CPWR spectra obtained with either p-polarized (TM; panels a and b), or s-polarized (transverse electric (TE); panels c and d) excitation light ($\lambda = 632.8$ nm), and a glass prism coated with either silver or gold layer with the optical parameters as indicated in Figure 1, overcoated with a 450-nm SiO$_2$ film. The emerging medium is water. The resonance spectra of silver (solid line), and gold (dashed line), are presented as reflectance versus either the incident angle (panels a and c), with constant value of light wavelength ($\lambda = 632.8$ nm), or the light wavelength (panels b and d), at constant value of incident angle ($\alpha = \alpha_R$, as indicated in panels a and c, are the incident angles at which resonance excited with light wavelength = 632.8 nm reaches its maximum, for silver and gold).
of k). In addition, the mass of the deposited layer can also be calculated, which allows binding isotherms to be measured.\(^{(17)}\) All of these characterizations can be obtained using a single device covered with a sensing layer, and using a measurement method that involves only a determination of reflected light intensity under total internal reflection conditions. Furthermore, because the electromagnetic field decays exponentially within the emerging medium, the measurement is sensitive only to the interface region between the dielectric overcoat and the emerging medium, and is not interfered with by the bulk properties of the medium. In addition, there is no limitation on the dielectric material that can be used in such coatings (as long as the optical characteristics are favorable), and therefore the dielectric film can be formed from any number of layers designed and optimized for different uses.\(^{(17)}\)

### 1.3 Advantages and Limitations of Surface Plasmon Resonance Spectroscopy in Peptide and Protein Analysis

As described above, SPs create a surface-bound evanescent electromagnetic wave which propagates along the surface of an active medium (usually a thin metallic film), with the electric field intensity maximized at this surface and diminishing exponentially on both sides of the interface. As a consequence of this property, the phenomenon has been utilized extensively in studies of surfaces and of thin dielectric films, including lipid, protein, and lipid–protein layers, deposited on the active medium. The SPR technique is able to probe both kinetic and thermodynamic processes, as well as to provide microstructural information, which makes it a very important component of the experimental methodology available to probe molecular interactions occurring at surfaces.\(^{(4,14,15,17,22)}\)

Further, it allows some of the limitations of other techniques to be overcome. For example, other methods often require one of the partners to be labeled in some way in order to allow it to be detected. Fluorescent probes, radioactive labels, and attachment of independently detectable molecules (e.g. enzymes) have all been used for this purpose. These suffer from the drawback that they may interfere with the binding of the labeled partner to the unlabeled one, or cause unwanted structural perturbations. SPR observations are based solely on the dielectric properties of molecules, or their intrinsic light absorption characteristics, and thus require no specific labeling. The more versatile CPWR technique offers a relatively simple optical method to obtain information about both mass (i.e. binding affinity) and structural parameters, including anisotropy in lipid and proteolipid films, overcoming the problems and challenges related to detecting small amounts of material located at the interface between two immiscible phases, which may be labile and structurally heterogeneous.\(^{(4,15,17)}\)

Although numerous other optical techniques have also been applied to such systems (e.g. ellipsometry, interferometry, spectrophotometry, and microscopy), the SPR methodology has some important advantages over all other optical techniques, as follows. It utilizes a relatively simple optical system, it has a superior sensitivity, and the complete system of measurement is located on the side of apparatus which is remote from the sample, and thus there is no optical interference from the bulk medium. Further, the surfaces of the sample need no extra treatment to increase reflectivity, because this is achieved by operating at the critical angle for total reflectance. Additional benefits include the fact that there are three parameters of the resonance that can readily be measured, thereby yielding much more information about the sample and changes within it than the simple interferometric step height used in other sensitive optical techniques. Finally, the method allows direct measurements of mass in real time. CPWR expands spectroscopic sensitivities and capabilities even further, allowing the measurement of anisotropies in both the refractive index and the extinction coefficient.

### 2 Sensitivity of the Surface Plasmon Resonance Method

The sensitivity, \(S\), of an SPR measurement can be defined as the change in reflectance, measured either at a specified incident angle, \(\alpha_1\), or a specified excitation wavelength, \(\lambda_1\), within the range of the resonance curve, divided by the change in one of the optical parameters, (Equations 6a and 6b):

\[
S_{\alpha_1} = \frac{dR(\alpha)}{dn \, dk \, d\alpha} \quad \text{(6a)}
\]

\[
S_{\lambda_1} = \frac{dR(\lambda)}{dn \, dk \, d\lambda} \quad \text{(6b)}
\]

respectively. As can be seen from the explicit expression for \(R\) given by the characteristic matrix of a thin film assembly\(^{(3)}\) the reflectance is not only a function of the optical parameters of the sensing layer, but also depends on the optical parameters of the incident and emerging media, as well as those of the metal film which generates the SPs. In addition, the refractive indices and extinction coefficients of these media are related to one another by the complex form of Snell’s Law, which complicates the function \(R\) even further. In general, however, changes in the experimental value of \(R\) are generated by two factors: the shift of the position and the change of the shape of
the resonance spectrum. The latter parameter is usually described either by the sharpness of the SPR spectrum, i.e. its half-width, or by the slope of the reflectance function, and characterizes the resolution in either the resonance angle or the resonance wavelength.

In general, the overall sensitivity of the SPR device depends on both the metallic-layer material (e.g. gold or silver), and the type of SPR being measured. The increase in the evanescent field is much smaller (about 2-fold) with gold than silver (see Figures 1–3), which translates into about a 4-fold smaller overall sensitivity for an SPR device based on gold.\(^{(4)}\) The different types of SPRs (Figures 1–3) show different distributions of the evanescent electromagnetic field within the resonator device, resulting in widely varying sensitivities. LRSPR has about 2.5-fold higher overall sensitivity than conventional SPR, whereas CPWR shows an even higher increase in sensitivity, about 3.5-fold for p-polarization and about 8-fold for s-polarization, as compared to conventional SPR.\(^{(17)}\) Therefore, the final design of an SPR device is usually a compromise between the different factors influencing overall sensitivity, durability, and any other requirements of the device for a specific practical application.

3 IMMOBILIZATION OF PROTEINS ON PLASMON-GENERATING SOLID SURFACES

The SPR (or CPWR) technique can only be applied to investigate surface or interfacial phenomena when combined with an appropriate thin metal (or dielectric) film surface which is modified to allow the desired types of molecular interactions to occur at the surface or interface. Therefore, one important function of such solid-surface modifications is to immobilize the molecules of interest at the interface. A second important feature of the surface modification is to prevent molecules on the solid surface from undergoing structural changes due to adsorption, which can result in a loss of biological activity or a modification of the thermodynamic properties of the system. This is especially important in the case of immobilization of proteins at a solid–liquid interface.

There are two principal techniques that have been employed in order to immobilize proteins at solid–liquid interfaces, while avoiding unwanted structural perturbations. The first of these involves transfer onto a solid surface of an immobilizing medium, for example, dextran gels,\(^{(23)}\) lipid monolayers generated at a liquid–gas interface by the Langmuir–Blodgett method,\(^{(24)}\) or lipid vesicles suspended in an aqueous solution,\(^{(25)}\) followed by binding of the protein to the immobilizing medium by electrostatic interactions, hydrophobic interactions, hydrogen bonding, etc. The second method uses self-assembly techniques that directly form an immobilization layer on a solid surface. The first of these involves chemical modification of the solid surface, whereas the most commonly used second method applies the principles governing the spontaneous formation of freely suspended lipid bilayer membranes within an orifice in a hydrophobic barrier separating two aqueous regions.\(^{(26,27)}\)

3.1 Chemical Modifications of the Surface

Chemical modifications usually involve formation of film coatings by covalent attachment to the solid surface. This type of surface modification includes alkyllamine surfactants on hydroxylated surfaces such as silica and aluminum oxide, alkane thiolates on gold, silver, and copper, alcohols and amines on platinum, and carboxylic acids on aluminum oxide and silver oxide.\(^{(10,12,27,28–32)}\) The technique allows formation of oriented monolayer films. If combined with polymeric material, such procedures can be used to create much thicker structures, as has been done in a commercially available SPR device, where an approximately 100–200-nm-thick layer of covalently bound dextran hydrogel has been produced on a thin gold film.\(^{(25)}\) The synthesis and characterization of coatings of organic surfactants on metal or metal oxide surfaces has become a separate field of physical chemistry.

Although both of these solid-surface modifications, i.e. thin monolayer coatings and thick layers of dextran hydrogel, have been successfully used in protein immobilization, they have some inherent limitations. In general, there are two types of restrictions:

1. those associated with the amount of biological material which can be immobilized at the modified surface; and
2. those related to the types of biological material that can be immobilized.

The first of these influences the dynamic concentration range (defined as the range below the saturation level) that can be measured by SPR. Thus, the quantity of immobilized molecules will be proportional to the amount of the chemical coating, and by increasing the thickness of the chemical coating to produce a three-dimensional multilayer surface, one can thereby increase the extent of molecule immobilization. However, this introduces some very serious disadvantages, which result both from complexities in the kinetic pattern of protein–protein interactions within the three-dimensional structure of the modifier, as well as from the exponentially decaying sensitivity of the SPR response across the thickness of the chemical modifier.\(^{(33)}\)
The second limitation of chemical modification procedures results from the fact that they generate either a densely packed monolayer of modifier or a three-dimensional hydrophilic gel. Although such systems have been used with water-soluble proteins they are not very well suited to the immobilization of integral membrane proteins, which require a lipid bilayer or a surfactant micelle to retain their native properties. Therefore, there have been some attempts to adjust the chemical surface modifications to allow membrane proteins to be immobilized at a solid–liquid interface, by combining them with Langmuir–Blodgett monolayers or by using lipid vesicles.

However, the use of self-assembled lipid bilayer membranes as described in the next section appears to be superior, and provides a more flexible and biocompatible environment.

### 3.2 Self-assembled Solid-supported Lipid Membranes as Biocompatible Matrices

The application of SPR to membrane proteins is more difficult than to water-soluble proteins, because the former materials require a hydrophobic environment, and they are especially difficult to maintain in a functional state. These two factors become even more important when the proteins have to be associated with a solid surface.

Several approaches to generating a surface coating that would be compatible with membrane proteins have been developed. As noted above, one such approach involves the transfer onto a solid surface of either monolayers generated at a liquid–gas interface by the Langmuir–Blodgett method, or lipid bilayer vesicles suspended in an aqueous solution. A second approach is based on self-assembly techniques that directly form a bilayer on a solid surface. Although both of these methodologies can produce a lipid bilayer film on a solid surface, the properties of the resulting membranes are quite different.

Tamm and McConnell have described the formation of a supported phospholipid bilayer generated by sequential transfer of two Langmuir–Blodgett monolayers from the air–water interface to the solid substrate, and Kalb et al. have developed a procedure for forming supported phospholipid bilayers by fusion of vesicles to supported phospholipid monolayers. These two techniques have been further elaborated by combining them with chemical modification of the solid surface (mainly by silanization and alkanethiolization). Although such planar supported lipid bilayer membranes can in principle be used in SPR measurements of membrane-associated proteins, a major limitation involves the difficulty of reconstituting transmembrane proteins. This is a result of a membrane-generating procedure in which two monolayers are transferred separately to form a bilayer system.

Generation of self-assembled lipid bilayers employs the principles that govern the spontaneous formation of a freely suspended lipid bilayer membrane within an orifice in a hydrophobic barrier separating two aqueous solutions. This procedure, when applied to a solid surface in contact with an aqueous medium, generates a lipid bilayer membrane which rests on an ultrathin water layer, which makes it freely supported and accessible for transmembrane proteins which usually protrude outside the membrane. Furthermore, because the membrane is formed from a lipid solution, it contains small amounts of hydrocarbon solvent molecules, which are incorporated within the lipid monolayers. This results in two significant alterations in the bilayer structure. It decreases the tilt angle of the aliphatic tails of the lipid molecules, that is it increases the thickness of the lipid bilayer, and, what is even more important in the context of the present applications, also separates the lipid molecules, introducing both more flexibility and extra space between the head groups. The method of preparation involves spreading a small amount of lipid bilayer-forming solution across a small hole in a Teflon® sheet that separates a metal (or semiconductor) support from an aqueous phase. The hydrophilic surface of the solid support, which is covered with an ultrathin water layer, attracts the polar headgroups of the lipid molecules, thus forming an adsorbed lipid monolayer with the hydrocarbon chains oriented toward the bulk lipid phase. Subsequent to this first step of lipid membrane formation, the main body of the sample cell is filled with an appropriate aqueous buffer solution. This initiates the second step, which involves a thinning process, that is formation of the second monolayer and a plateau–Gibbs border that anchors the bilayer film to the Teflon® spacer. The plateau–Gibbs border, which results from the membrane-forming process, and is composed of the lipid solution used to generate the membrane, plays the role of a reservoir of lipid and solvent molecules, which can be moved either into or out of the storage region during the process of bilayer development or membrane protein incorporation.

### 4 BIOLOGICAL APPLICATIONS OF SURFACE PLASMON RESONANCE SPECTROSCOPY

As a consequence of the abovementioned characteristics, SPR is ideally suited to studying both structural and mass changes of thin films, including molecular interactions such as protein–protein or lipid–protein, occurring at
surfaces and interfaces. These can be examined using either steady-state SPR spectroscopy, when Equation (7) applies:

\[ R = f(\alpha, \text{time})_{\text{time}=\text{const}, \ \lambda=\text{const}}; \]

or 

\[ R = f(\lambda, \text{time})_{\text{time}=\text{const}, \ \alpha=\text{const}} \]  

(7)
or time-resolved SPR spectroscopy, when Equation (8) is valid:

\[ R = f(\alpha, \text{time})_{\text{time}=\text{const}}; \]

or 

\[ R = f(\lambda, \text{time})_{\text{time}=\text{const}} \]  

(8)
and can be applied to a wide range of materials. The time-resolved mode expands the capability of SPR techniques to allow probing of the dynamics of structural and mass alterations of thin films.

4.1 Structural Parameters of Biomolecular Films

The influence of optical parameters on the angular (or wavelength) position, the angular (or wavelength) width, and the depth of the SPR spectrum is completely contained in the characteristic matrix of the thin-film assembly which allows a determination of their values. The experimental SPR (or CPWR) spectra interpreted in the context of the characteristic matrix of the assembly allow a unique evaluation of \( n, k, \) and \( t. \) The evaluation procedure is based on fitting a theoretical resonance curve to the experimental one. In addition, the CPWR method provides a means for determining the optical parameters using both TM \((p)\) and TE \((s)\) polarizations of the excitation light, resulting in two values of the refractive index \((n_p, n_s)\), and two values of the extinction coefficient \((k_p, k_s)\). These parameters can then be used to calculate the anisotropy of \( n \) and \( k \), thereby describing the degree of both molecular order (by the anisotropy in \( n \)) and orientation of chromophoric groups attached to the molecules comprising the thin film (by the anisotropy in \( k \)). Such information, taken together with the film thickness \((t)\), provides insights into the microscopic structure of the film. Furthermore, the optical parameters can also be employed to calculate the mass of a deposited thin layer (see next section for details).

4.2 Evaluation of Binding Affinities

As noted above, the values of the \( n, k, \) and \( t \) parameters of a thin-film layer deposited on the surface of a metal film contain information about the amount of material in the layer. The adsorbed mass can be calculated from both extinction coefficient and refractive index. The former is based on the relationship of mass (or concentration) of the adsorbed substance and the amount of light which is absorbed, expressed by the well-known Lambert–Beer law. In CPWR experiments the mass (or concentration), can be calculated from the value of the extinction coefficient, \( k \), which is a measure of the light absorption in the medium and is related to the more familiar absorption coefficient, \( \beta \), which describes the absorption of light of wavelength \( \lambda \) per unit of absorbing substance thickness and concentration \( C \), by Equation (9):

\[ k = \beta \left( \frac{C}{4\pi} \right) \]  

(9)

There are two different ways of calculating the adsorbed mass from the refractive index value. The first of these is based on the assumption that the refractive index increment, \( dn/dC \), is independent of the concentration, \( C \), of the adsorbed substance. If this is so, the surface mass density, \( m_s \), i.e. the amount of material per unit surface area, can be evaluated by Equation (10):

\[ m_s = t \left( \frac{n - n_2}{dn/dC} \right) \]  

(10)

where \( n \) and \( n_2 \) are refractive indices of the adsorbed thin film and the emerging medium, respectively, and \( dn/dC \) is the refractive index increment of the adsorbed substance. Equation (10) can, of course, only be used if the refractive index increment is known, and depends on the assumption that the value of the increment is constant over the concentration range of the adsorbed material.

The second method of mass calculation is based on the Lorentz–Lorenz relation, which can be presented in the most general case, i.e. when the deposited layer contains a mixture of substances, by Equation (11):

\[ \frac{n^2 - 1}{n^2 + 2} = A_1M_1 + A_2M_2 + \cdots \]  

(11)

where \( A_i \) and \( M_i \) are the molar refractivity and the number of moles of substance per unit volume, respectively. The most straightforward application of this aspect of SPR (or CPWR) technology is the measurement of binding isotherms and binding affinities. Steady-state SPR measurements, by determining mass density changes occurring in molecular assemblies accompanying binding interactions, allow an evaluation of the binding affinities.

4.3 Determination of Rate Constants for Binding Reactions

The measurements can be greatly simplified when the SPR (CPWR) technique is used in a kinetic mode, i.e. when reflectance is only a function of time at \( \alpha = \text{const} \) and \( \lambda = \text{const} \). Under the stated conditions, the reflectance is taken at one specific point of the resonance curve as a function of time and is described by
Equation (12):
\[ R = f(\text{time})_{\lambda = \text{const, } \lambda' = \text{const}} \]  

Such a simplified experimental approach can provide a means for real-time analysis of molecular interactions and allows one to directly probe the molecular interaction, including protein–protein and lipid–protein interactions, by monitoring association and dissociation processes in real time,\(^{(53,39)}\) under the following conditions. First, the measurement must be performed with an optically isotropic system characterized by a refractive index value that is independent of the light polarization. Second, the binding of one molecule to another that is immobilized on the surface of an SPR device must produce a change in the refractive index, \( n \), of the interface that results in an alteration of the SPR spectrum. This latter condition is only valid when the SPR-exciting light wavelength is outside of an absorption spectral region of both interacting molecules, and when the interaction does not induce any structural changes in the interface. Third, the changes in \( n \) are assumed to be proportional to the surface concentration of bound molecules, \( C_i \), i.e. 
\[ \frac{dn}{dC} = \text{constant over the whole concentration range.} \]
This assumption can give rise to some error, especially at high concentrations where the proportionality might not be fulfilled. Fourth, the changes in \( n \) must only cause a shift of the resonance curve without any alterations in its shape, which is a simplification of the theoretical influence of \( n \) on the resonance curve as determined by the characteristic matrix of the thin-film assembly. Under these conditions, changes in the \( n \)-value can be measured directly by the shift of the SPR resonance curve, which is the basic requirement of using kinetic measurements to monitor association and dissociation processes in real time.

1 Introduction

1.1 Crystals and Symmetry

In a crystal, atoms or molecules are arranged in a three-dimensionally periodic manner by translational symmetry. The crystal is formed by a three-dimensional stack of unit cells which is called the crystal lattice (Figure 1a and b). The unit cell is built up by three non-collinear vectors a, b and c. In the general case these vectors have unequal magnitudes and their mutual angles deviate from 90°. The arrangement of the molecule(s) in the unit cell may be asymmetrical but very often

1 INTRODUCTION

1.1 Crystals and Symmetry

In a crystal, atoms or molecules are arranged in a three-dimensionally periodic manner by translational symmetry. The crystal is formed by a three-dimensional stack of unit cells which is called the crystal lattice (Figure 1a and b). The unit cell is built up by three non-collinear vectors a, b and c. In the general case these vectors have unequal magnitudes and their mutual angles deviate from 90°. The arrangement of the molecule(s) in the unit cell may be asymmetrical but very often
In crystals, only 1-, 2-, 3-, 4- and 6-fold rotations are allowed. This follows from the combination of the lattice properties with rotational operations. Other possible symmetry elements are mirror plane $m$, inversion center and combination of rotation axis with inversion center (inversion axis). These are the point group symmetries. They can only occur among each other in a few certain combinations of angles. Other angle orientations would violate the lattice properties. The number of all possible combinations reveals the 32 point groups. The crystal morphology obeys the point group symmetries.

Adding an inversion center to the point group symmetry leads to the 11 Laue groups. These are of importance for the symmetry of X-ray diffraction patterns. Their symbols are: $\bar{1}, 2\bar{m}, 2\bar{mmm}, 3, 3\bar{m}, 4\bar{m}, 4\bar{mmm}, 6\bar{m}, 6\bar{mmm}, m3, m\bar{3}m$. Proteins and nucleic acids are chiral molecules. Therefore, they can crystallize only in the 11 enantiomorphic point groups: 1, 2, 3, 4, 6, 23, 222, 32, 422, 622 and 432.

The combination of point group symmetries with lattices leads to seven crystal systems,
triclinic, monoclinic, orthorhombic, trigonal, tetragonal, hexagonal and cubic, with 14 different Bravais-lattice types which can be primitive, face-centered, all-face-centered and body-centered. Furthermore, additional symmetry elements are generated having translational components such as screw axes or glide mirror planes. There exist 230 space groups of which 65 are enantiomorphic (for chiral molecules such as proteins). Figure 3 shows the graphical representation for the space group \( P2_12_12_1 \) as listed in the *International Tables for Crystallography*.(1) The asymmetric unit is one fourth of the unit cell and can contain one or several molecules. Multimeric molecules may have their own symmetries which are called noncrystallographic symmetries. Here axes which are 5-fold, 7-fold, etc., are also allowed.

### 1.2 Protein Solubility

Figure 4 shows a typical phase diagram illustrating the solubility properties of a macromolecule. In the labile phase crystal nucleation and growth compete whereas in the metastable region only crystal growth appears. In the unsaturated region crystals dissolve. The solubility of proteins is influenced by several factors, as follows.

#### 1.2.1 Ionic Strength

A protein can be considered as a polyvalent ion and therefore its solubility can be discussed on the basis of the Debye–Hückel theory.

In aqueous solution, each ion is surrounded by an “atmosphere” of counter ions. This ionic atmosphere influences the interactions of the ion with water molecules and hence the solubility.

1.2.1.1 “Salting-in” At low ionic concentration, the “ionic atmosphere” increases the solubility as it increases the possibilities for favorable interactions with water molecules. We obtain (Equations 1 and 2)

\[
\log \frac{S}{S_0} = \frac{AZ_+Z_-\sqrt{\mu}}{1 + aB\sqrt{\mu}}
\]

where \( \mu = \) ionic strength, \( S = \) solubility of the salt at a given ionic strength \( \mu \), \( S_0 = \) solubility of the salt in absence of the electrolyte, \( Z_+ \), \( Z_- \) = ionic charge of salt ions, \( A \), \( B \) = constants depending on the temperature and dielectric constant, \( a \) = average diameter of ions and \( c_j \) = concentration of the \( j \)th chemical component.

Ions with higher charge are more effective for changes in solubility. Most salts and proteins are more soluble in low ionic strength than in pure water. This is termed as “salting-in” (Figure 5).

1.2.1.2 “Salting-out” At higher ionic strength the ions compete for the surrounding water. Therefore, water molecules are taken away from the dissolved agent and the solubility decreases according to Equation (3):

\[
\log S - \log S_0 = \frac{AZ_+Z_-\sqrt{\mu}}{1 + aB\sqrt{\mu}} - K_s\mu
\]

The term \( K_s\mu \) predominates at high ionic strengths, which means that “salting-out” is then proportional to the ionic strength (Figure 5). In a medium with low ionic strength the solubility of a protein can be decreased by increasing or decreasing the salt concentration. Salts with small, highly charged ions are more effective than those with large, lowly charged ions. Ammonium sulfate is often used because of its high solubility.

#### 1.2.2 pH and Counterions

A protein is more soluble the larger is its net charge. The minimum solubility is found at the isoelectric...
point. The net charge is zero and hence the packing in the solid state (in the crystal) is possible owing to electrostatic interactions without the accumulation of a net charge of high energy. All “salting-out” curves are parallel, $K_s$ remains constant and $S_0$ varies with pH (Figure 6a and b). In some cases the isoelectric point is different at low and high ionic strength owing to the interactions of the protein with counterions which can cause a net charge at the pH of the isoelectric point.

1.2.3 Temperature

Many factors governing protein solubility are temperature dependent. The dielectric constant decreases with increasing temperature. In the solution energy, $\Delta G = \Delta H - T \Delta S$, the entropy term has an increasing influence with increasing temperature. The temperature coefficient of the solubility depends on other conditions (ionic strength, presence of organic solvents, etc.). At high ionic strength most proteins are less soluble at 25°C than at 4°C, e.g., the temperature coefficient is negative. The opposite is valid for low ionic strength.

1.2.4 Organic Solvents

The presence of organic solvents leads to a decrease in the dielectric constant. This causes an augmentation of the electric attraction between opposite charges on the surface of the protein molecule and hence to a reduction in solubility. In general, the solubility of a protein is reduced in the presence of an organic solvent if the temperature decreases. Often organic solvents denature proteins. Therefore, one should work at low temperatures.

1.3 Experimental Techniques

The whole field of macromolecular crystallography has been excellently reviewed in Volumes 114 and 115 and Volumes 276 and 277 of Methods in Enzymology. A collection of review articles concerning the theory and practice of crystallization of biomacromolecules is given in Part A of Carter and Sweet.

A protein preparation to be used in crystallization should be “pure” or “homogeneous” at a level that established chromatographic methods are providing (protein content ≥ 95%). Furthermore, it should meet the requirements of “structural homogeneity”. These requirements can be enumerated as follows. It is first necessary to prepare the protein in an isotopically pure state free from other cellular proteins. It may then be necessary to maintain the homogeneity of the protein preparation against covalent modification during crystallization by adding inhibitors of sulfhydryl group oxidation, proteolysis and the action of reactive metals. It may be necessary to suppress the slow denaturation/aggregation of the protein and to restrict its conformational flexibility to reduce the entropic barrier to crystallization presented by extensive conformational flexibility.

For the crystallization of biomacromolecules a broad spectrum of crystallization techniques exists. The most

---

**Figure 5** Solubility of carboxyhemoglobin in various electrolytes at 25°C. (Reproduced by permission of the American Society for Biochemistry and Molecular Biology, from Green.)
common techniques are described here. The oldest and simplest method is batch crystallization (Figure 7a). In batch experiments, vials containing supersaturated protein solutions are sealed and left undisturbed. In microbatch methods, a small (2–10 µL) droplet containing both protein and precipitant is immersed in an inert oil which prevents droplet evaporation. In the case that ideal conditions for nucleation and growth are different, it is useful to undertake the separate optimization of these processes. This can be done by seeding, a technique where crystals are transferred from nucleation conditions to those that will support only growth (Figure 7b). For macroseeding, a single crystal is transferred to an etching solution, then to a solution of optimal growth. In microseeding experiments, a solution containing many small seed crystals, occasionally obtained by grinding a larger crystal, is transferred to a crystal growth solution.

The method of crystallization by vapor diffusion is depicted in Figure 8(a). In this method, unsaturated precipitant-containing protein solutions are suspended over a reservoir. Vapor equilibration of the droplet
and reservoir causes the protein solution to reach a supersaturation level where nucleation and initial crystal growth occur. Changes in soluble protein concentration in the droplet are likely to decrease supersaturation over the time course of the experiment. The vapor diffusion technique can be carried out as hanging drop or sitting drop method.

In crystallization by dialysis, the macromolecular concentration remains constant as in batch methods (Figure 8b) because the molecules are forced to stay in a fixed volume. The solution composition is changed by diffusion of low-molecular-weight components through a semipermeable membrane. The advantage of dialysis is that the precipitating solution can be easily changed. Dialysis is also uniquely suited to crystallizations at low ionic strength and in the presence of volatile reagents such as alcohols.

1.4 Crystallization Screenings

Screening schemes have been developed which change the most common parameters of this multiparameter problem such as protein concentration, the nature and concentration of the precipitant, pH and temperature. Each screening can be extended by adding specific additives in low concentrations that affect the crystallization. Sparse matrix crystallization screens are widely applied. The sparse matrix formulation allows one to screen efficiently a broad range of the most popular and effective salts (e.g. ammonium sulfate, sodium and potassium phosphate, sodium citrate, sodium acetate, lithium sulfate), polymers [e.g. poly(ethylene glycol) (PEG) of different molecular masses (from 400 to 8000)] and organic solvents [e.g. 2,4-methylpentanediol (MPD), 2-propanol, ethanol] versus a wide range of pH. Another approach is the systematic screening of the statistically most successful precipitants. A single precipitant is screened at four unique concentrations versus seven precise levels of pH between 4 and 10. Such grid screens can be done with ammonium sulfate, PEG 6000, MPD, PEG 6000 in the presence of 1.0 M lithium chloride or sodium chloride. For the crystallization of membrane proteins [see Michel] for each detergent which is necessary to make the membrane protein soluble a whole grid screen or sparse matrix screen must be constructed. In principle, all three techniques can be applied for the different screening schemes but mostly the vapor diffusion technique is applied because it is easy to use and the protein consumption is low. For a typical broad screening, about 2 mg of protein are sufficient. Chryschem plates (sitting drop) or Linbro plates (hanging drops) may be used for the vapor diffusion crystallization screening experiments. Once crystals have been obtained, their size and quality can be optimized by additional fine screens around the observed crystallization conditions. General rules do not exist that indicate which method for crystallization one has to use for which type of protein. Suggestions for crystallization conditions to be tested can be obtained from the Biological Macromolecule Crystallization Database.

2 EXPERIMENTAL TECHNIQUES

2.1 X-ray Sources

2.1.1 Conventional X-ray Generators

X-rays are produced when a beam of high-energy electrons, which have been accelerated through a voltage \( V \) in a vacuum, hit a target. An X-ray tube run at voltage \( V \) will emit a continuous X-ray spectrum with a minimum wavelength given by Equation (4):

\[
\lambda_{\text{min}} = \frac{hc}{eV} = \frac{12398}{V}
\]

with \( \lambda \) in Ångströms (1 Å = 10^{-10} m) and \( V \) in volts. The critical voltage, \( V_0 \), which is required to excite the characteristic line of a particular element can be calculated from the corresponding wavelength for the appropriate absorption edge. For the copper absorption edge \( \lambda_{\text{Cu}} = 1.380 \) Å, Hence (Equation 5):
Provided that \( V > V_0 \), the characteristic line spectra will be produced (Figure 9). The oldest and cheapest X-ray sources are sealed X-ray tubes. The cathode and anode are situated under vacuum in a sealed glass tube and the heat generated at the anode is removed by a water cooling system. For the generation of higher intensities, as needed in protein crystallography, one has to use a rotating anode (Figure 10). Here the anode is rotated, which allows a higher power loading at the focal spot. In protein crystallography copper targets are usually taken. The used take-off angle is near 4°, which results in apparent focal spot sizes of about 0.3 \( \times \) 0.3 mm.

### 2.1.2 Synchrotron Radiation

As electrically charged particles such as electrons or positrons of high energy are kept under the influence of magnetic fields and travel in a pseudocircular trajectory, synchrotron radiation is emitted and can be used in many different types of experiments [for a comprehensive discussion of synchrotron radiation in macromolecular crystallography, see Helliwell\(^{11}\)]. The particles are injected into the storage ring directly from a linear accelerator or through a booster ring. They circulate in a high vacuum for several hours at a relative constant energy. To keep the bunched particles traveling in a nearly circular path, a lattice of bending magnets is set up around the storage ring. As the particle beam traverses each magnet, the path of the beam is altered, and synchrotron radiation is emitted. The loss of energy of the particle beam is compensated by a radiofrequency input at each cycle. The synchrotron radiation can be channeled through different beamlines for use in research.

Other types of magnets – insertion devices called “wigglers” and “undulators” – can be assembled in the storage ring. Unlike the bending magnets, the primary purpose of which is to maintain the circular trajectory, wigglers and undulators are used to increase the intensity of the emitted radiation. Bending magnets and wigglers cause a continuous spectrum of radiation. In contrast, the radiation produced by an undulator has a discontinuous spectrum and can be tuned to various wavelengths. The importance of synchrotron radiation for macromolecular crystallography lies in the high brilliance (photons s\(^{-1}\) mrad\(^{-2}\) mm\(^{-2}\) per \( \Delta \lambda / \lambda \); that is, how small is the source and how well collimated are the X-rays?) of the beam, the high intensity and the tunability of the wavelength in the relevant range from 0.5 to 3.0 Å. The time structure of the beam is of interest for time-resolved crystallography.\(^{12}\) The particles circulate in bunches with widths of 50–150 ps and repeat every few microseconds.

About 15 synchrotron radiation facilities equipped with beamlines for macromolecular crystallography are available throughout the world operated at energies from about 1.5 to 6–8 GeV for third-generation machines. An aerial view of the European Synchrotron Radiation Facility (ESRF) in Grenoble, a third-generation machine, is shown in Figure 11. The ESRF storage ring is operated at 6 GeV and has a circumference of 844.39 m. Its critical wavelength, \( \lambda_c \), is 0.6 Å.

---

**Figure 9** X-ray spectrum emitted from a copper anode. It shows the continuous “Bremsstrahlung” starting at \( \lambda_{\text{min}} \) and the two characteristic copper lines \( \lambda \) K\( \alpha_1 \) = 1.5405 Å (superposition of \( \lambda \) K\( \alpha_1 \) = 1.5405 Å and \( \lambda \) K\( \alpha_2 \) = 1.5443 Å) and \( \lambda \) K\( \beta \) = 1.3922 Å.

**Figure 10** Schematic drawing of a rotating anode tube. Take-off angle is near 4°. For copper the tube is normally operated at 50 kV high tension and 100 mA cathode current.
2.1.3 Monochromators

In the majority of applied diffraction techniques, monochromatic X-rays are used. Therefore, the emitted white radiation of X-rays must be further monochromatized. With copper Kα radiation generated by a sealed or rotating anode tube, the Kβ radiation can be removed with a nickel filter. Much better results can be achieved with a monochromator. The simplest monochromator is a piece of a graphite crystal which reflects the copper Kα radiation at a Bragg angle of 13.1° and a glancing angle of 26.2°. Improved beam focusing is obtained by a double mirror system. The mirror assembly is composed of two perpendicular bent nickel-coated glass optical flats, each with translation, rotation and slit components housed in a helium gas flashed chamber, which is commercially available (Molecular Structure Corporation, The Woodlands, TX, USA). The prototype and basic theory in the use of this system were discussed in detail by Phillips and Rayment.\(^{(13)}\)

For synchrotron radiation with its much higher intensity, germanium or silicon single crystals can be applied as monochromators which filter out a bandwidth of \(\delta \lambda / \lambda\) from \(10^{-4}\) to \(10^{-5}\), two orders of magnitude smaller than with graphite. Single or double monochromators can be used which are either flat or bent. The bent monochromators have the advantage that they simultaneously focus the beam. The double monochromator (Figure 12) has the advantage that the emergent monochromatic beam is parallel to and only slightly displaced from the incident synchrotron radiation beam. This makes necessary only small adjustments of the X-ray optics and detector arrangement when it is tuned to another wavelength compared with a single monochromator where the whole X-ray diffraction assembly must be moved.

2.2 Detectors

2.2.1 General Components of an X-ray Diffraction Experiment

A principal arrangement for a macromolecular X-ray diffraction experiment is depicted in Figure 13. The primary beam leaves the X-ray source and passes the X-ray optics, which may be a simple collimator or the various types of monochromators or mirror systems described above and terminated with a collimator. The crystal is mounted on a goniometer head either in a quartz capillary or in a cryo-loop shock frozen at low temperature. The goniometer head is attached to a device which can perform spatial movements of the crystal around the center of the crystal. The simplest kind of such a movement is the rotation of the crystal about a spindle axis as indicated in Figure 13. This device can be a multiple axis goniostat (2–4 axes) which allows the crystal to be brought into any spatial orientation around its center. The
X-ray detector which registers the diffracted intensities is mounted on a device which permits the translation and rotation of the detector. If the active area of the detector is large enough to collect all generated diffracted beams at a given wavelength, detector rotation is not necessary and the detector is arranged normal to the primary beam. A small piece of lead is placed in the path of the primary beam just behind the crystal to prevent damage to the detector and superfluous gas scattering.

The classical detectors in macromolecular crystallography have been photographic films and single-photon counters. The photographic films were used on specially designed X-ray cameras and the single-photon counters on four-circle diffractometers. The main disadvantage of these detectors was their low sensitivity and with films the limited dynamic range (1 : 200). Over the last 15 years, powerful detectors have been developed which will be discussed briefly. These new detectors have almost completely replaced photographic films and single-photon counters.

2.2.2 Image Plates
An image plate (IP) consists of a support (either a flexible plastic plate or a metal base) coated with a photostimulable phosphor (150 µm) and a protective layer (10 µm). The photostimulable phosphor is a mixture of very thin crystals of e.g. BaF(Br, I) : Eu²⁺ and an organic binder. This phosphor can store a fraction of the absorbed X-ray energy by electrons trapped in color centers. It emits photostimulated luminescence whose intensity is proportional to the absorbed X-ray intensity, when later stimulated by visible light. The wavelength of the photostimulated luminescence (λ ≈ 390 nm) is reasonably separated from that of the stimulating light (λ ≈ 633 nm, in practice a red laser), allowing it to be collected by a conventional high quantum efficiency photomultiplier tube. The output of the photomultiplier is amplified and converted to a digital image, which can be processed by a computer. The residual image on the IP can be erased completely by irradiation with visible light, to allow repeated use.

IPs have several excellent performance characteristics as integrating X-ray area detectors that make them well suited in X-ray diffraction. The sensitivity is at least 10 times higher than for X-ray films and the dynamic range is much broader (1 : 10⁴−10⁵). Important for synchrotron radiation is their high sensitivity at shorter wavelengths (e.g. 0.65 Å). A disadvantage is the relatively long readout times for each exposure (from 45 s to several minutes). IP diffractometer systems are commercially available from several companies. All systems work reliably and deliver good-quality data. A photograph of the newest IP system produced by Mar Research (Hamburg, Germany) is shown in Figure 14.

2.2.3 Gas Proportional Detectors
As X-ray counters, gas proportional detectors provide unrivaled dynamic range and sensitivity for photons in the range important for macromolecular crystallography (for a review, see Kahn and Fourme[14]). The classical gas proportional detector is a multiwire proportional chamber (MWPC), widely used as an in-house detector with conventional X-ray sources. Two MWPC diffractometer systems are commercially available. Gas proportional detectors use as a first step the absorption of an X-ray photon in a gas mixture high in xenon or argon. This photoabsorption produces one electron–ion pair whose total energy is just the energy of the initial X-ray photon. The ion returns to its neutral state either by emission of Auger electrons or by fluorescence. Since the kinetic energy of these first electrons is far greater than the energy of the first ionization level of the xenon or argon atoms, fast collisions with atoms (or molecules) in the gas very quickly produce a cascade of new electron–ion pairs in a small region extending over a few hundred micrometers around the conversion point. The total number of primary electrons that are produced during this process is proportional to the energy of the absorbed X-ray photon and is thus a few hundred for ~10 keV photons. These primary electrons then drift to the nearest anode wire where an ionization avalanche of 10 000–1 000 000 as many ion pairs results. The motion of the charged particles in this avalanche (chiefly the motion of the heavy positive ions away from the anode wire) causes a negative-going pulse on the anode wire and positive-going pulses on a few of the nearest wires in the back (cathode) wire plane (see Figure 15).
Disadvantages of the MWPC detector are the limited counting rate due to the build-up of charges in the chamber and limitations in the readout electronics and the lower sensitivity at shorter wavelengths. This makes the application of MWPCs with synchrotron radiation poorly effective.

### 2.2.4 Charge-coupled Device-based Detectors

A remarkable development for the use with synchrotron radiation is the design and construction of charge-coupled device (CCD) detectors (for a review, see Westbrook and Naday). CCDs were developed originally as memory devices, but the observation of localized light-induced charge accumulation in CCDs quickly led to their development as imaging sensors. These CCD detectors are integrating detectors like the conventional X-ray sensitive film, IPs and analog electronic detectors using either silicon intensified target (SIT) or CCD sensors. Integrating detectors have virtually no upper rate limits because they measure the total energy deposited during the integration period (although individual pixels may become saturated if the signal exceeds its storage capacity). The first commercially available analog electronic detector was the fast area television detector (FAST) detector produced by Enraf-Nonius (Delft, The Netherlands). This detector contained a SIT vidicon camera as an electronically readable sensor. The SIT vidicon exhibits higher noise than CCDs, which have therefore replaced SIT sensors during the past few years. Because of their high intrinsic noise, detectors with SIT vidicon sensors need an analog image-amplification stage and this limits the overall performance of such detectors. Several CCD detector systems have also been developed that incorporate image intensification. The most important development in detector design for macromolecular crystallography has been the incorporation of scientific-grade CCD sensors into instruments with no image intensifier. These detector designs are based on direct contact between the CCD and a fiber-optic taper. There are several commercial systems available based on this construction (MAR Research, Hamburg Germany; Hamlin Detector).

A schematic representation of such a detector is shown in Figure 16. An X-ray phosphor (commonly Gd$_2$O$_2$:Tb) is attached to a fiber-optic faceplate which is tightly connected to a fiber-optic taper. The X-ray sensitive phosphor surfaces at the front convert the incident X-rays into a burst of visible-light photons. Although it is possible to permit the X-rays to strike the CCD directly, this method has several drawbacks, such as radiation damage to the CCD, signal saturation and poor efficiency. The use of a larger phosphor as active detector area and the demagnifying fiber-optic taper is also necessary because the size of the scientific-grade CCD sensors is not as large as needed for the demands of the X-ray diffraction experiment. The fiber-optic taper is then bonded to the CCD which is connected to the electronic readout system. The CCD must be cooled to temperatures ranging from $-40^\circ$C to $-90^\circ$C, depending on the various systems. The great advantage of CCD detectors is their short readout time, which lies in the range from 1 to a few seconds.

![Figure 15](image1.png) **Figure 15** Expanded view of a MWPC showing the anode plane sandwiched between the two cathode planes. A is the position of the avalanche. The centers of the induced charge distributions are used to determine the coordinates, $x$ and $y$, of the avalanche. (Reproduced by permission of Academic Press, Inc., from Kahn and Fourme.)

2.3 Crystal Mounting and Cooling

2.3.1 Conventional Crystal Mounting

The purpose of crystal mounting is to isolate a single crystal from its growth medium so that it can be used in the X-ray diffraction experiment to study its diffraction properties. It is important that the manipulation of the crystal introduce as little damage as possible to its three-dimensional structure. The most important aspect of crystal mounting is to preserve the crystal in its state of hydration. This is accomplished by sealing the crystal in a thin-walled (0.001 mm thick) glass or quartz capillary tube. The important steps in conventional crystal mounting are illustrated in Figure 17(a–c). The crystal must be dislodged from the surface on which it grew, then it may be drawn into the capillary using suction from a small-volume (0.25 mL) syringe, micropipet or mouth aspirator which are connected to the funnel of the capillary by a flexible plastic hose of appropriate diameter. Next, the capillary should be inverted to allow the crystal to fall to the inner meniscus. Then the surrounding solution may be removed using thin strips of filter paper or by a small glass pipet. The extent to which the crystal should be dried must be determined by experience. The final step is to place a small-volume of mother liquor in the capillary and seal both ends. The capillary is then glued to a metal base which can be attached to a goniometer head.

2.3.2 Cryocrystallography

Many macromolecular crystals suffer from radiation damage when exposed to X-rays with energies and intensities as used in macromolecular X-ray diffraction experiments with both conventional sources and synchrotron radiation. A possibility for reducing radiation damage of the crystal during the measurement is to cool the crystal to low temperatures, usually to 100 K (for a review on cryocrystallography, see Rodgers\(^{16}\)). For this purpose the crystal is flash-frozen to prevent ice formation or damage to the crystal. One method of crystal treatment is the removal of external solution by transferring the crystal in a small drop to a hydrocarbon oil and either teasing the liquid away or drawing it off with filter paper or a small pipet. The oil-coated crystal is then mounted on a glass fiber or small glass “spatula”. Oil protects the crystal from drying and acts as an adhesive that hardens on cooling to hold the sample rigidly. Much more frequently used is a technique in which the crystal is suspended in a film of cryoprotectant-containing harvest buffer. The loop is supported by a fine wire or pin, which itself is attached to a steel base used for placing the assembly on a goniometer head and in storing mounted crystals. Once in the loop, the crystal is cooled to a temperature at which the increasing viscosity of the liquid prevents molecular rearrangement. The rate of cooling must be rapid enough to reach this point before ice-crystal nucleation occurs. Two methods are used: cooling directly in the gas stream of a cryostat or plunging the crystal into a cryogenic liquid. The first method is explained in Figure 18(a) and (b). The loop assembly (with crystal) is attached to the goniometer head with the cold stream deflected. Then the cold stream is unblocked to flash-freeze the crystal. In this gas-stream position the goniometer head must be heated to prevent ice formation on the goniometer head. Cryostats and cryocrystallographic tools are commercially available.
Cryocrystallography has had a great impact on macromolecular crystallography by dramatically increasing the lifetime of a crystal during the X-ray experiment allowing, for example, the collection of several data sets from one crystal at different wavelengths using synchrotron radiation.

2.4 Data Collection Techniques

2.4.1 Rotation Method

Most macromolecular X-ray diffraction systems use the rotation method for data collection [a detailed discussion of the rotation method is given by Arndt and Wonnacott(18)]. For each crystal a reciprocal lattice can be constructed which is very useful in the interpretation of crystallographic crystal diffraction experiments. Diffraction theory (discussed later) tells us that an X-ray reflection is generated when a point of this reciprocal lattice lies on a sphere of radius $1/\lambda$ whose origin is $1/\lambda$ away from the origin of the reciprocal lattice in the direction of the primary beam (Figure 19). The direction of such a diffracted beam is along the connection of the center of the so-called Ewald sphere (radius $1/\lambda$) and the intersection of the reciprocal lattice point on the Ewald sphere. Owing to certain factors which will be discussed later, the apparent reciprocal lattice extends to a given radius only which defines the resolution sphere. To bring all reciprocal lattice points within the resolution sphere into the reflection position, the crystal must be rotated around its center. Nearly all macromolecular X-ray diffraction systems apply the rotation technique in the normal beam case where the rotation axis is normal to the incident X-ray beam. Rotating the crystal around $360^\circ$ brings all reciprocal lattice points within the resolution sphere in the reflection position except for the region between the rotation axis and the Ewald sphere, which is therefore called the blind region. This region can be collected when the crystal has been brought into another orientation. The diffracted beams are usually registered with a flat detector at distance $D$ from the crystal which is also normal to the primary beam. To avoid overlapping of reflection spots on the detector, the crystal is rotated by rotation angle increments which can vary from tenths of degrees to 1 to a few degrees depending on the size of the crystal unit cell, crystal mosaicity, beam collimation and other factors. Each individual exposure is processed and electronically stored in a computer. These raw data images are evaluated subsequently with relevant computer programs (discussed in some detail later) to give the intensities and geometric reference values (indices) for each collected intensity.

![Figure 19](image2.png)

Figure 19 Diffraction geometry in the rotation method usually applied in macromolecular X-ray diffraction systems.
2.4.2 Precession Method

The rotation method delivers a distorted image of the reciprocal lattice for each geometry of the detector (flat or curved) and orientation with respect to the rotation axis. An undistorted image of the reciprocal lattice can be obtained by using the precession method.\(^{(19)}\) The principle of this technique is shown in Figure 20. The detector is a flat film. During the motion of a given reciprocal lattice plane (in Figure 20 a so-called zeroth plane going through the origin O of the reciprocal lattice) the flat detector must always be parallel to this reciprocal lattice plane to obtain an undistorted image of this plane. The normal of the reciprocal lattice plane and consequently also the detector are inclined with respect to the primary X-ray beam by an angle $\mu$. When the normals of the reciprocal lattice plane and the detector carry out a concerted precession motion of angle $\mu$, a circular region of the reciprocal lattice plane is registered on the detector (these regions are shown as dashed circles in Figure 20). In a precession camera construction, the crystal and the film cassette are both held in a universal joint which are linked so that the film and crystal move together in phase with precession angle $\mu$. In Figure 20 the joints are symbolized as forks and their linkage by a line. Parallel to the zeroth reciprocal lattice plane is a set of lattice planes that also carry out this precession movement. The parts of them that are swung through the Ewald sphere also give rise to an image on the flat detector (first and second reciprocal lattice layers are also indicated in Figure 20). The images of these layers would superimpose on the detector and use of the technique in this way is denoted the screenless precession method. The insertion of a screen with a suitable annular aperture between the crystal and the detector at an appropriate distance can be used to screen out the desired reciprocal layer. This screen is also inclined by the precession angle $\mu$ and is coupled to the concerted precession movement of crystal and film cassette. The strength of the precession technique is that in addition to the undistorted imaging of the reciprocal lattice planes, the indexing of the diffraction spots is straightforward and the symmetry of the diffraction pattern is readily obtained by inspection. For this reason, the precession method has been broadly applied in macromolecular crystallography for a long time. The replacement of film by the new generation of detectors has almost completely stopped the use of the precession method. Nevertheless, the use of a precession camera has great teaching benefits in becoming familiar with the reciprocal lattice concept.

3 PRINCIPLES OF X-RAY DIFFRACTION BY A CRYSTAL

3.1 Scattering of X-rays by an Atom

A component of the electrical field of the incident wave has the following form (Equation 6) in free space referred to an origin at $x = 0$:

$$E(x) = E_0 \exp[2\pi i (v t - x s_0)]$$

where $s_0 =$ wave vector of incident wave, $v = c/\lambda =$ frequency, $\lambda =$ wavelength and $s_0 = 1/\lambda =$ absolute value of incident wave vector. This wave interacts with a scattering center at position $r$ (Figure 21). The electric field component of the incident wave causes the electron at position $r$ to oscillate. Together with the positively charged nucleus of the atom, which does not oscillate, this can be considered as a classical dipole-oscillator. This dipole-oscillator emits a spherical wave which is denoted as a scattered wave and can be given in the following form

![Figure 20](image) Principle of the precession method [modified from Buerger\(^{(19)}\)].

![Figure 21](image) Scattering of a planar X-ray wave by an electron at position $r$ with respect to origin O.
(Equations 7 and 8):
\[
E_{sc} = CE(r) e^{-2\pi i s_0 r_1} \quad (7)
\]
\[
E_{sc} = CE_0 e^{-2\pi i s_0 r_1} \quad (8)
\]

The phase-angle-dependent factor has been omitted. The amplitude of the scattered wave is proportional to the amplitude \(E(x)\) of the wave incident at \(r\). This gives the factor \(E(r)\). \(C\) is a proportionality factor taking into account peculiarities of the scattering center. The factor \(1/r_1\) considers the conservation of the scattered energy flux. We add all wavelets scattered from different volume elements of an atom to get the total amplitude of the scattered wave at point \(R\) relative to the origin \(O\) in the atom.

Equations (9–12) follow from Figure 21:
\[
r + r_1 = R \quad (9)
\]
\[
r_1^2 = (R - r)^2 = R^2 + r^2 - 2rR \cos(r, R) \quad (10)
\]
\[
r_1 = R \left[ 1 - \frac{2r}{R} \cos(r, R) \right] + \frac{r}{R} \quad (11)
\]
\[
r_1 \approx R \left[ 1 - \frac{r}{R} \cos(r, R) + \cdots \right] \quad (12)
\]

where \((r/R)^2\) and higher terms were neglected in the expansion of the square root. It follows that (Equation 13):
\[
r_1 \approx R - r \cos(r, R) \quad (13)
\]

Now we can combine the spatial phase factors in the equation for \(E_{sc}\). With the approximation for \(r_1\) we obtain Equation (14):
\[
e^{-2\pi i s_0 r_1} = e^{-2\pi i s_0 R} e^{-2\pi i [s_0 r - r \cos(r, R)]} \quad (14)
\]

As \(s_0 = s\) and \(s\) parallel to \(R\), we obtain Equation (15):
\[
s_0 r \cos(r, R) = s r \cos(r, s) = sr \quad (15)
\]

It follows for the phase factor (Equation 16):
\[
e^{-2\pi i (s_0 r - s \alpha)} = e^{-2\pi i s_0 R} e^{-2\pi i [s_0 r - s \alpha]} = e^{-2\pi i s_0 R} e^{2\pi i [s \alpha - s_0]} \quad (16)
\]

Now we can write for the wave scattered by a center at \(r\) (Equation 17):
\[
E_{sc}(r_1) = \left( CE_0 e^{-2\pi i s_0 R} e^{2\pi i r_1} \right) e^{2\pi i (r - s_0)} \quad (17)
\]

In a useful approximation, \(r_1\) has been replaced by \(R\) in the denominator.

In general, the scattering from an atom comes from the distribution of electrons in the atom. If the scattering of a volume element \(dv\) of the atom is proportional to the local electron density \(\rho(r)\), then the scattering amplitude will be proportional to the integral (Equation 18):
\[
f(S) = \int_{\text{vol. of atom}} \rho(r) \exp(2\pi i r S) dv = f_1 \exp(2\pi i r S) \quad (18)
\]

with \(S = s - s_0\).

### 3.2 Scattering of X-rays by a Unit Cell

A unit cell may contain \(N\) atoms at positions of their internal origins at \(r_j (j = 1, 2, 3, \ldots, N)\) with respect to the origin of the unit cell (Figure 22). For atom 1 we obtain Equation (19):
\[
f_1 = \rho(r) \exp[2\pi i (r_1 + r)] dv = f_1 \exp(2\pi i r S) \quad (19)
\]

with (Equation 20)
\[
f_1 = \rho(r) \exp(2\pi i r_1 S) dv \quad (20)
\]

where \(f_1\) is the atomic form factor for atom 1. It reflects the characteristics of the scattering of the individual atoms and is real if the wavelength of the incident X-ray is not close to an absorption edge of the atom. The atomic form factor \(f\) is equal to \(Z\), the ordinary number of the scattering atom, at a diffraction angle of 0° and decreases with increasing diffraction angle.

For \(N\) atoms this adds up to the total scattered wave of a unit cell \(G(S)\) (Figure 23) according to Equation (21):
\[
G(S) = \sum_{j=1}^{N} f_j \exp(2\pi i r S) \quad (21)
\]

Figure 22 Atomic positions in a unit cell.
3.3 Scattering of X-rays by a Crystal

3.3.1 One-dimensional Crystal

In a one-dimensional crystal the unit cells are separated by the unit cell vector \( \mathbf{a} \). The contribution of the scattered wave from the unit cell at the origin of the crystal is \( G(\mathbf{S}) \). All scatterers in the second unit cell are displaced by the vector \( \mathbf{a} \) relative to the origin, which introduces a corresponding phase factor and reveals for the second unit cell relative to the origin

\[
G(\mathbf{S})/\exp(-2\pi i \mathbf{a} \cdot \mathbf{S})
\]

For the \( n \)th unit cell relative to the origin we obtain

\[
G(\mathbf{S})/\exp(-2\pi i n \mathbf{a} \cdot \mathbf{S})
\]

This sums up for the total wave to Equation (22):

\[
\mathbf{F}(\mathbf{S}) = \sum_{n=1}^{T} G(\mathbf{S}) \exp(2\pi i n \mathbf{a} \cdot \mathbf{S})
\]

Generally, \( \mathbf{F}(\mathbf{S}) \) is of the same order of magnitude as \( G(\mathbf{S}) \) and no strong scattering effect is observed (Figure 24a). However, when \( 2\pi n \mathbf{a} \cdot \mathbf{S} = 2\pi h \) or an integral multiple of \( 2\pi \) or \( \mathbf{a} \mathbf{S} = h \) (\( h \) is an integer), the waves add up constructively to a scattered wave proportional to \( T[G(\mathbf{S})] \) (Figure 24b). \( T = 10^5 \) for a 1 mm long crystal with a 100 Å lattice constant. The intensity distribution of the scattered waves is concentrated around the values where \( \mathbf{a} \mathbf{S} \) is equal to an integer and depends on the number of contributing unit cells. The more unit cells are contributing, the sharper is the concentration of the intensity around these values.

3.3.2 Three-dimensional Crystal

In this case, the unit cell is spanned by the unit cell vectors \( \mathbf{a}, \mathbf{b} \) and \( \mathbf{c} \) and is repeated periodically by the corresponding vector shifts in the respective spatial directions. This means that we will obtain scattered waves of measurable intensities when the three subsequent conditions are fulfilled (Equation 23):

\[
a \mathbf{S} = h; \quad b \mathbf{S} = k; \quad c \mathbf{S} = l
\]

These conditions are known as Laue equations.

If we neglect the proportionality constant \( T \) we obtain Equation (24) for the total scattered wave for a three-dimensional crystal with a unit cell containing \( N \) atoms:

\[
\mathbf{F}(\mathbf{S}) = \sum_{j=1}^{N} f_j \exp(2\pi i \mathbf{r}_j \cdot \mathbf{S})
\]

with (Equation 25)

\[
\mathbf{r}_j = a x_j + b y_j + c z_j
\]
Hence we have (Equations 26 and 27)

\[
r_S = x_0 \mathbf{a} + y_0 \mathbf{b} + z_0 \mathbf{c}
\]

\[= h x_i + h y_j + l z_j\]  

(26)

(from Laue’s equation) and

\[
\mathbf{F}(hkl) = \sum_{j=1}^{N} f_j \exp(2\pi i (hx_i + ky_j + lz_j))
\]

\[= |\mathbf{F}(hkl)| e^{i \langle hkl \rangle}\]  

(27)

with \(|\mathbf{F}(hkl)|\) – amplitude and \(\alpha\) – phase angle. We obtain

the intensity of the scattered wave as the structure

factor \(\mathbf{F}(hkl)\) multiplied by its complex conjugate value

giving Equations (28):

\[I(hkl) = |\mathbf{F}(hkl)|^2\]  

(28)

3.4 The Reciprocal Lattice and Ewald Construction

In section 2.4 we mentioned the usefulness of the concept of

the reciprocal lattice in understanding the diffraction

of X-rays from a crystal. Now we have the necessary

relations for the derivation of the reciprocal lattice. One

can write the scattering vector \(\mathbf{S}\) as Equation (29):

\[\mathbf{S} = h_x \mathbf{a}^* + k_y \mathbf{b}^* + l_z \mathbf{c}^*\]  

(29)

where \(\mathbf{S}\) is a vector in reciprocal space with the metric

\(\mathbf{a}^*, \mathbf{b}^*, \mathbf{c}^*\). The relation to the direct space with metric \(\mathbf{a}, \mathbf{b}, \mathbf{c}\) is still unknown. The vector \(\mathbf{S}\) must obey the Laue

equations (Equation 30):

\[\mathbf{a S} = (h_x \mathbf{a}^* + k_y \mathbf{b}^* + l_z \mathbf{c}^*) = h\]

\[= h_x \mathbf{a a}^* + k_y \mathbf{a b}^* + l_z \mathbf{a c}^* = h\]  

(30)

This is fulfilled only when \(\mathbf{a a}^* = 1, h_x = h\) and \(\mathbf{a b}^*\) and

\(\mathbf{ac}^* = 0\). Similar equations can be derived for the other

two Laue conditions. Thus, vector \(\mathbf{S}\) is a vector of a

lattice in reciprocal space. The relation between direct

and reciprocal lattice is given by the following set of nine

equations (Equations 31–39):

\[\mathbf{aa}^* = 1\]  

(31)

\[\mathbf{ba}^* = 0\]  

(32)

\[\mathbf{ca}^* = 0\]  

(33)

\[\mathbf{ab}^* = 0\]  

(34)

\[\mathbf{bb}^* = 1\]  

(35)

\[\mathbf{cb}^* = 0\]  

(36)

\[\mathbf{ac}^* = 0\]  

(37)

It follows from these that \(\mathbf{a}^* \perp \mathbf{b}, \mathbf{c}\); \(\mathbf{b}^* \perp \mathbf{a}, \mathbf{c}\); \(\mathbf{c}^* \perp \mathbf{a}, \mathbf{b}\);

and vice versa. The metric relations can also be derived

from these relations. They are given explicitly e.g. in

Drenth. It means that the inverse lattice vectors are

perpendicular to the plane which is spanned by the two

other non-inverse lattice vectors.

Bragg’s law can be derived now by inspection of

Figure 25. The wave vectors for the incident wave \(s_0\) and

the scattered wave \(s\) have the same absolute value

of \(1/\lambda\). Vector \(\mathbf{S}\) must be a vector of the reciprocal lattice

and its absolute value is equal to \(d^*\). From Figure 25 we

obtain Equations (40–42):

\[\sin \theta = \frac{d^*}{2 \lambda}\]  

(40)

\[\lambda = \frac{2 \sin \theta}{d^*}\]  

(41)

\[\lambda = 2d \sin \theta\] for \(n = 1\)  

(42)

The general equation for Bragg’s law is Equation (43):

\[2d \sin \theta = n \lambda\]  

(43)

where \(n\) is the order of reflection and \(d\) the interplanar
distance in the direct lattice.

The Ewald construction is contained in Figure 19. A

sphere of radius \(1/\lambda\) is drawn. The origin of the reciprocal lattice

is located where the wave vector \(s_0\) ends on the Ewald sphere. A
diffracted beam is generated if a reciprocal lattice vector \(d^* h k l\)
with an absolute value of \(1/d_{h k l}\) cuts the Ewald sphere. The beam is diffracted

in the direction of the connection of the origin of the

Ewald sphere and the intersection point of the reciprocal lattice point on the Ewald sphere. The diffraction pattern of a lattice is itself a lattice with reciprocal lattice dimensions.

3.5 The Temperature Factor

The thermal motion of the atoms causes a decrease of the scattering power by a factor of \( \exp\left(\frac{-B\sin^2 \theta}{\lambda^2}\right) \) with (Equation 44)

\[
B = 8\pi^2 \bar{u}^2
\]  

(44)

where \( \bar{u} \) is the mean displacement of the atoms due to the thermal motion. The atomic scattering factor \( f \) must be multiplied with this factor. In this model the thermal motion has been assumed to be isotropic. Therefore, \( B \) is denoted the isotropic temperature factor. In crystals this is usually not the case and the thermal motion is described by a tensor ellipsoid. Here we obtain a set of six independent anisotropic temperature factors. In protein crystallography, isotropic \( B \) values for each atom of the molecules are used normally. The thermal motion of the atoms is one main reasons for the fall-off of the diffraction intensity especially at higher diffraction angles. This limits the possible recordable number of diffraction spots and, as will be seen later, the resolution of the diffraction experiment.

3.6 Symmetry in Diffraction Patterns

An X-ray diffraction data set from a crystal represents its reciprocal lattice with the corresponding diffraction intensities at the reciprocal lattice points \((hkl)\). As the reciprocal lattice is closely related to its direct partner it reveals symmetries, lattice properties and other peculiarities (e.g. systematic extinctions) that are connected to the direct crystal symmetry such as unit cell dimensions and space group. A detailed discussion of this problem is given in Buerger.\(^\text{22}\)

In the case of real atomic scattering factors \( f \) the diffraction intensities are centrosymmetric according to Friedel’s law (Equation 45):

\[
I(hkl) = I(\overline{hkl})
\]  

(45)

This is illustrated in Figure 26(a) and (b). The square of a complex number is the product of this number by its complex conjugate. This is shown for \( F(hkl) \) in Figure 26(a) and for \( F(\overline{hkl}) \) in Figure 26(b). The resulting intensities are equal in both cases.

3.7 Electron Density Equation and Phase Problem

Inspection of the equation for the structure factor (Equation 46):

\[
F(S) = \sum_{j=1}^{N} f_j \exp 2\pi ir_jS
\]

(46)

shows that it is the Fourier transform of the electron density \( \rho(r) \).

The electron density \( \rho(r) \) is then the inverse Fourier transform of the structure factor \( F(S) \) according to Equation (47):

\[
\rho(r) = \frac{1}{\text{vol. of diffraction space}} \int F(S) \exp -2\pi irS \, dv
\]  

(47)

The integration is replaced by summation since \( F(S) \) is not continuous and is nonzero only at the reciprocal lattice
points. Hence we have (Equation 48)
\[
\rho(xyz) = \frac{1}{V} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F(hkl) \times \exp[-2\pi i(hx + ky + lz)]
\]
(48)

Knowing the structure factors (Equation 49):
\[
F(hkl) = |F(hkl)|e^{i\alpha(hkl)}
\]
(49)
one can calculate the electron density distribution in the unit cell and thus determine the atomic positions of the scattering molecule(s). Unfortunately, the measured quantities are only the absolute values \(|F(hkl)|\) of the structure factor. Information on the phase angles \(\alpha(hkl)\) is lost during the diffraction experiment. The determination of these phases is the basic problem in any crystal structure determination and we discuss the methods for solving the phase problem later.

3.8 The Patterson Function

The measured X-ray intensities are proportional to the square of the absolute value of the structure factor according to Equation (28). Would it be possible to use the intensities directly to calculate from these a function which contains structural information? The answer is “yes”. If one calculates a convolution of the electron which contains structural information? The answer is

\[
|F(hkl)|^2
\]

one can be calculated, from which it is possible to locate the heavy atoms.

3.9 Integrated Intensity Diffracted by a Crystal

Real crystals are not perfect. They can be regarded as consisting of small blocks of perfect crystals (sizes in the range of 0.1\(\mu m\)) which have an average tilt angle among each other of 0.1–0.5° for protein crystals and which diffract independently of each other. Such a real crystal is denoted a mosaic crystal. The total energy, \(E_b\), in a diffracted beam for a mosaic crystal rotating with uniform angular velocity \(\omega\) through the reflecting position in a beam of X-rays of incident intensity \(I_0\) is given by Darwin’s equation (Equation 52):

\[
E(h) = \frac{I_0}{\omega} \frac{e^4}{m^2 c^4} \frac{LAV_z}{V^2} |F(h)|^2
\]
(52)

where \(\lambda = \) wavelength of X-rays, \(e = \) electronic charge, \(m = \) mass of electron, \(c = \) velocity of light, \(p = \) polarization factor, \(L = \) Lorentz factor (geometrical factor taking into account the relative time each reflection spends in the reflection position), \(A = \) absorption factor, \(V = \) volume of the unit cell and \(V_z = \) irradiated crystal volume.

Owing to the mosaicity (0.1–0.5°), each reflection has a corresponding reflection width. The integrated intensity equation is valid under the assumption that apart from ordinary absorption the incident intensity, \(I_0\), is constant within the crystal (kinematic theory of X-ray diffraction) and the mosaic blocks are so small that no multiple scattering occurs within an individual mosaic block. The integrated intensity depends on \(\lambda\) to the third power. Increasing the wavelength causes appreciably stronger diffraction intensities but is accompanied by larger absorption. Cu Kα radiation with a wavelength of 1.5418 \(\AA\) is an optimal choice for protein crystallography when using X-ray generator sources. Also important is the dependence of the integrated intensity on the unit cell volume \(V\) by its negative second power. Doubling of the unit cell volume with twice as many molecules, taking into account the increase in \(|F(h)|^2\) by having now 2\(n\) molecules per unit cell, reduces the average intensity for the reflected beams by a factor of two.

In Equation (52) \((\lambda^2/\omega V^2) \times (e^4/m^2 c^4) \times V_z \times I_0\) is a constant for a given experiment. The corrected intensity on a relative scale \(I(h)\) is obtained from Equation (53):

\[
I(h) = \frac{E(h)}{p \times L \times A}
\]
(53)

3.10 Intensities on an Absolute Scale

The corrected intensity on a relative scale \(I(h)\) can be converted to an intensity given by Equation (54):

\[
I(\text{abs, } h) = |F(h)|^2
\]
(54)
on an absolute scale by applying a so-called Wilson plot. The basis for this plot is an equation which connects the average intensity on an absolute scale with the average intensity on a relative scale by a scale factor $C$ and considers the isotropic thermal motion of the scattering atoms by the temperature factor given in Equation (44). This is written in the form of Equation (55):

$$\ln \frac{I(h)}{\sum f_i^2} = \ln C - 2B\frac{\sin^2 \theta}{\lambda^2}$$  \hspace{1cm} (55)

This is the equation of a straight line. $B$, the overall temperature factor, and $C$, the scale factor, can be obtained by plotting $\ln \frac{I(h)}{\sum f_i^2}$ against $(\sin^2 \theta)/\lambda^2$.

### 3.11 Resolution of the Structure Determination

The concept of resolution in X-ray diffraction has the same meaning as the concept in image formation in the optical microscope.

After the Abbe theory, we obtain Equation (56):

$$d_m = \frac{\lambda}{2NA}$$  \hspace{1cm} (56)

where $NA$ is the numerical aperture of the objective lens. In protein crystallography, the nominal resolution of an electron density map is expressed in $d_m$, the minimum interplanar spacing for which $F$s are included in the Fourier series. The maximum attainable resolution at a given wavelength is $\lambda/2$. For copper Kα radiation it is 0.7709 Å and would suffice to determine protein structures at atomic resolution (the distance of a carbon–carbon single bond is about 1.5 Å). However, usually the thermal vibrations of the atoms in a protein crystal are so high that the diffraction data cannot be observed to the full theoretical resolution limit. The polypeptide chain fold can be determined at a resolution of better than 3.5 Å. A medium-resolution structure is in the resolution range of 3.0–2.2 Å and makes the amino acid side-chains clearly visible. A high-resolution structure has a nominal resolution better than 2.2 Å and can be as good as 1.2 Å. In such structures the main-chain carbonyl oxygens become visible as prominent bumps and at a resolution better than 2.0 Å aromatic side-chains acquire a hole in the middle of their ring systems. For some very well diffraction crystals from small proteins, diffraction data extending to resolutions below 1.2 Å could be collected with synchrotron radiation. Such structures reveal real atomic resolution where each atom is visible as an isolated maximum in the electron density map.

### 3.12 Diffraction Data Evaluation

The analysis and reduction of diffraction data from a single crystal consists of seven major steps: (1) visualization and preliminary analysis of the raw, unprocessed data; (2) indexing of the diffraction patterns; (3) refinement of the crystal and detector parameters; (4) integration of the diffraction spots; (5) finding the relative scale factors between measurements; (6) precise refinement of crystal parameters using the whole data set; and (7) merging and statistical analysis of the measurements related by space-group symmetry. When using electronic area detectors with short read-out times such as CCD or MWPC detectors it is possible to collect diffraction images with small rotational increments (0.05–0.2°). In this case, the reflection profile over the crystal rotation angle can be registered giving a three-dimensional picture of the spot. The evaluation of such diffraction data can be done with computer programs MADNES, XDS, the San Diego programs and related programs XENGEN and X-GEN. IP systems with their longer read-out times are operated in a film-like mode with rotational increments of 0.5–2.0°. Here, mainly the program systems MOSFLM and Denzo are applied. The most important developments in the data evaluation of macromolecular diffraction measurements are autoindexing, profile fitting, transformation of data to a reciprocal-space coordinate system and demonstration that a single rotation image contains all of the information necessary to derive the diffraction intensities from that image.

Scaling, merging and statistical analysis of the intensity data are either done with corresponding programs of the CCP4 program suite or with Scalepack. The principles of these operations are given in the manuals for these programs. With modern data-collection methods, the completeness should approach 100% (including the low-resolution data which are very important for molecular replacement), the ratio $I/\sigma(I)$ should be significant even for the highest resolution shell and undue emphasis should not be given to the reliability factor for merging the data (R-merge) unless factors such as multiplicity are taken into account. Nowadays it is customary using synchrotron radiation techniques and fast CCD detectors to collect as much data as possible (before radiation damage becomes significant) in order to produce good statistics.

### 3.13 Solvent Content of Protein Crystals

The Matthews parameter $V_M$, which is defined according to Equation (57):

$$V_M = \frac{V_{\text{unit cell}}}{M_{\text{Prot}}}$$  \hspace{1cm} (57)
where \( V_{\text{unit cell}} \) is the volume of the unit cell and \( M_{\text{Prot}} \) is the molecular mass of the protein in the unit cell, has values that are in the range \( 1.6 - 3.5 \text{ Å}^3 \text{ daltons} / N \) for proteins. This allows a rough estimation of the number of molecules in the unit cell.

Furthermore, \( V_M \) can be used for the assessment of the solvent content of a protein crystal. Calling \( V_{\text{Prot}} \) the crystal volume occupied by the protein, \( V_p' \), its fraction with respect to the total crystal volume \( V \) and \( M_{\text{Prot}} \) the mass of protein in the cell, we obtain Equation (58):

\[
V_p' = \frac{V_{\text{Prot}}}{V} = \frac{V_{\text{Prot}}/M_{\text{Prot}}}{M_{\text{Prot}}/V} \tag{58}
\]

The first term is the specific volume of the protein, the second the reciprocal of \( V_M \) and, remembering that the molecular weight is expressed in daltons, we have Equation (59):

\[
V_p' = \frac{1.6604}{d_{\text{Prot}} V_M} \tag{59}
\]

Taking \( 1.35 \text{ g cm}^{-3} \) as the protein density, we obtain as a first approximation Equations (60) and (61):

\[
V_p' \approx \frac{1.23}{V_M} \tag{60}
\]

\[
V_{\text{Solv}}' = 1 - V_p' \tag{61}
\]

The solvent content in a protein crystal may vary from 75 to 40%.

4 METHODS FOR SOLVING THE PHASE PROBLEM

4.1 Isomorphous Replacement

4.1.1 Preparation of Heavy Metal Derivatives

If one can attach one or several heavy metal atoms at defined binding site(s) to the protein molecules without disturbing the crystalline order, one can use such isomorphous heavy atom derivatives for the phase determination. The lack of isomorphism can be monitored by a change in the unit cell parameters compared with the native crystal and a deterioration of the quality of the diffraction pattern. The preparation of heavy atom derivatives is undertaken by soaking the crystals in mother liquor containing the dissolved heavy metal compound. Soaking times may be in the range from several minutes to months. Concentrations of the heavy metal compound may vary from tenths of millimolar to 50 mM.

Favorite heavy atoms are Hg, Pt, U, Pb, Au, rare earth metals, etc. Potential ligands can be classified as hard and soft ligands according to Pearson. Hard ligands are electonegative and undergo electrostatic interactions. In proteins, such ligands are glutamate, aspartate, terminal carboxylates, hydroxyls of serines and threonines and in the buffer acetate, citrate and phosphate. Soft ligands are polarizable and form covalent bonds such as cysteine, cystine, methionine and histidine in proteins and Cl\(^-\), Br\(^-\), I\(^-\), S-ligands, CN\(^-\) and imidazole in the buffer solution.

Metals are classified according to their preference for hard or soft ligands. Class (a) metals bind preferentially to hard ligands. They comprise the cations of A-metals such as alkali and alkaline earth metals, the lanthanides, some actinides and groups IIIA, IVA and VA of the transition metals. Class (b) metals are rather soft and polarizable and can form covalent bonds to soft ligands. They include heavy metals at the end of the transition metal groups such as Hg, Pt and Au. Thus, in the protein, the class (b) metals Hg, Pt and Au and complex compounds of them bind to soft ligands such as cysteine, histidine or methionine and the class (a) metals U and Pb to hard ligands such as the carboxylate groups of glutamate or aspartate.

4.1.2 Single Isomorphous Replacement

The structure factor \( F_{PH} \) for the heavy atom derivative structure (Figure 27) becomes (Equation 62):

\[
F_{PH} = F_P + F_H \tag{62}
\]

where \( F_P = \) structure factor of the native protein and \( F_H = \) contribution of the heavy atoms to the structure factor of the derivative. The isomorphous differences, \( F_{PH} - F_P \), which can be calculated from experimental

![Figure 27 Vector diagram for the vector addition of the structure factor of the native protein \( F_P \) and the heavy atom contribution \( F_H \) to the heavy atom derivative structure factor \( F_{PH} \).](image-url)
intensity data sets of the native and derivative protein, correspond to the distance CB in Figure 27 and are given by Equation (63):

$$F_{PH} - F_P = F_H \cos(\alpha_{PH} - \alpha_H) - 2F_P \sin^2 \left( \frac{\alpha_P - \alpha_{PH}}{2} \right)$$

(63)

If \(F_H\) is small compared with \(F_P\) and \(F_{PH}\), the sine term will be very small and we have (Equation 64)

$$F_{PH} - F_P \approx F_H \cos(\alpha_{PH} - \alpha_H)$$

(64)

When vectors \(F_P\) and \(F_H\) are collinear, then (Equation 65)

$$|F_{PH} - F_P| = F_H$$

(65)

The square of the isomorphic differences, \(F_{PH} - F_P\), can be used as coefficients in a Patterson synthesis. We get

$$(F_{PH} - F_P)^2 = 4F_P^2 \sin^4 \left( \frac{\alpha_P - \alpha_{PH}}{2} \right) \tag{i}$$

$$+ F_P^2 \cos^2(\alpha_{PH} - \alpha_H) \tag{ii}$$

$$- 4F_P F_H \sin^2 \left( \frac{\alpha_P - \alpha_{PH}}{2} \right) \times \cos(\alpha_{PH} - \alpha_H) \tag{iii}$$

(66)

It is a theorem of Fourier theory that the Fourier transform of the sum of Fourier coefficients is equal to the sum of the Fourier transforms of the individual Fourier coefficients. Here there are three different terms. \((\alpha_P - \alpha_{PH})\) is small if \(F_H\) is small and term (i) which gives the protein–protein interaction will be of low weight. The transform of term (iii) is zero if sufficient terms are included. However, if \(F_H \ll F_P\), \((\alpha_{PH} - \alpha_H)\) is effectively random and term (ii) will give heavy atom vectors with half the expected peak heights (Equation 67):

$$F_H^2 \cos^2(\alpha_{PH} - \alpha_H) = \frac{1}{2} F_H^2 + \frac{1}{2} F_H^2 \cos 2(\alpha_{PH} - \alpha_H) \tag{67}$$

with the second term on the right contributing only noise to the Patterson map because the angles \(\alpha_{PH}\) and \(\alpha_H\) are not correlated. Such an isomorphous heavy atom difference Patterson map allows the determination of the positions of the heavy metals on the condition of isomorphism and a not too large heavy atom partial structure. The interpretation of these difference Patterson maps is undertaken by vector verification routines which are part of the CCP4 program suite.\(^{36}\) In these routines the asymmetric unit of the unit cell is systematically scanned by calculating on each scan point the corresponding heavy atom–heavy atom vectors, determining their peak height in the Patterson map and evaluating a meaningful correlation value (e.g. the sum of the correlated maxima). Prominent heavy atom sites should show up with high correlation values.

It is important to know what intensity changes are generated by the attachment of heavy atoms to the macromolecule. According to Crick and Magdoff,\(^{39}\) the relative root mean square intensity change is given by Equation (68) for centric reflections:

$$\sqrt{\frac{\langle \Delta I \rangle^2}{I_P}} = 2 \times \frac{I_H}{I_P} \tag{68}$$

and by Equation (69) for acentric reflections:

$$\sqrt{\frac{\langle \Delta I \rangle^2}{I_P}} = \sqrt{2} \times \frac{I_H}{I_P} \tag{69}$$

where \(I_H\) is the average intensity of the reflections if the unit cell were to contain the heavy atoms only and \(I_P\) is the average intensity of the reflections of the native protein. Attaching one mercury atom \((Z = 80)\) to a macromolecule with varying molecular mass and assuming 100% occupancy gives the following average relative changes in intensity: 0.51 for 14 000 Da, 0.25 for 56 000 Da, 0.18 for 112 000 Da, 0.13 for 224 000 Da and 0.09 for 448 000 Da. From this estimation it is evident that with increasing molecular mass more heavy atoms or for large molecular masses heavy metal clusters such as Ta\(_6\)Br\(_{12}^+\)(\(^{40}\)) must be introduced to generate intensity changes which can be statistically measured (precision for intensity measurements between 5 and 10%) and which are sufficient for the phasing.

The phase calculation for single isomorphous replacement can be seen from the so-called Harker construction for this case (Figure 28). \(F_H\), which can be calculated from the known heavy atom positions, is drawn in its negative direction from the origin O ending at point A. Circles are drawn with radii \(F_P\) and \(F_{PH}\) from points O and A, respectively. The connections of the intersection points of both circles B and C with origin O determine two possible phases for \(F_P\). This means that the single isomorphous replacement leaves an ambiguity in the phase determination for the acentric reflections.

### 4.1.3 Multiple Isomorphous Replacement

The phase ambiguity can be overcome if two or more isomorphous heavy atom derivatives are used which exhibit different heavy atom partial structures. In Figure 29 the Harker construction for two different heavy atom derivatives is shown. In addition to Figure 28, \(-F_H\) is drawn from the origin O and a third circle with radius \(F_{PH}\) is inserted around its end-point B. The intersection point, H, of all three circles determines the protein phase, \(\alpha_P\). In the case of \(n\) isomorphous derivatives there are \(n + 1\) circles which have one common intersection point.
4.2 Anomalous Scattering

4.2.1 Theoretical Background

So far, in the normal Thomson scattering of X-rays the electrons in the atom have been treated as free electrons that vibrate as a dipole-oscillator in response to the incident electromagnetic radiation and generate elastic scattering of the X-rays. However, the electrons are bound to atomic orbitals in atoms and this treatment is valid only if the frequency \( w \) of the incident radiation is large compared with any natural absorption frequency \( w_{kn} \) of the scattering atom. For the light atoms in biological macromolecules (H, C, N, O, S, P) with frequency \( w \) of the used radiation (in the \( \lambda \) range of 0.4 to 3.5 Å), this condition is fulfilled and these atoms really scatter normally. For heavier elements the assumption \( w \gg w_{kn} \) is no longer valid and the frequency \( w \) may be higher for some and lower for other absorption frequencies. If \( w \) is equal to an absorption frequency \( w_{kn} \), absorption of radiation will occur which is manifested by the ejection of a photoelectron with an energy corresponding to the ionization energy for this electron. This transition goes to a state in the continuous region because the discrete energy states are all occupied in the atom. The absorption frequencies for the K, L, or M shells are connected with the corresponding absorption edges which are characterized by a sharp drop in the absorption curve (absorption vs \( \lambda \)) at the edge position. It is evident that the scattering from the electrons with their resonance frequencies close or equal to the frequency of the incident radiation will deliver a special contribution which is called anomalous scattering.

The classical treatment [see James^{41}] is briefly outlined. It is assumed that the atoms scatter as if they contain electric dipole-oscillators having certain definite natural frequencies. The classical differential equation of the motion of a particle of mass \( m \) and charge \( e \) in an alternating electric field \( E \) is Equation (70):

\[
\ddot{x} + k \dot{x} + w_s^2 x = \frac{eE_0 \text{e}^{i\omega t}}{m}
\]

where the damping factor, \( k \), is proportional to the velocity of the displayed charge and \( w_s \) is the natural circular frequency of the dipole if the charge is displaced. The steady-state solution for this equation for the moment of the dipole which executes forced oscillations of frequency \( \omega \) under the action of the incident wave is Equation (71):

\[
M = e \mathbf{x} = \frac{e^2}{m} \frac{E_0 \text{e}^{i\omega t}}{w_s^2 - w^2 + ikw}
\]

The amplitude \( A \) of the scattered wave at unit distance in the equatorial plane is given by Equation (72):

\[
A = \frac{e^2}{mc^2} \frac{w^2 E_0}{w_s^2 - w^2 + ikw}
\]
that scattered by a free classical electron under the same conditions. This amplitude at unit distance and in the equatorial plane is given by Equation (73):

\[ A' = -\frac{e^2}{m c^2} E_0 \]  

(73)

Hence we obtain Equation (74) for \( f' \):

\[ f = \frac{w^2}{w^2 - w^2_s} - ikw \]  

(74)

If \( f \) is positive the scattered wave has a phase difference of \( \pi \) with respect to the primary beam (introduced by the negative sign in the equation for \( A' \)). If \( w \gg w_s, f \) is unity. In the case of \( w \ll w_s, f \) is negative and the dipole then scatters a wave in phase with the primary beam. Equation (74) can be split into real and imaginary parts so that we obtain Equation (75):

\[ f = f' + if'' \]  

(75)

with (Equations 76 and 77)

\[ f' = \frac{w^2(w^2 - w^2_s)}{(w^2 - w^2_s)^2 + k^2w^2} \]  

(76)

\[ f'' = \frac{kw^2}{(w^2 - w^2_s)^2 + k^2w^2} \]  

(77)

We now extend this for an atom consisting of \( s \) electrons each acting as a dipole-oscillator with oscillator strength \( g(s) \) and resonance frequency \( w_s \). We have to multiply the contribution for each electron by \( g(s) \) and form the sum over all electrons. For the total real part of the atomic scattering factor we obtain Equation (78):

\[ f' = \sum_s \frac{g(s)w^2_s}{w^2 - w^2_s} \]  

(78)

which assumes \( w \) is not very nearly equal to \( w_s \), and a small damping, \( f' \) can be written as Equation (79):

\[ f' = f_0 + \Delta f' = \sum_s g(s) + \sum_s \frac{g(s)w^2_s}{w^2 - w^2_s} \]  

(79)

For free electrons we have \( w_s = 0 \) and \( f' = f_0 = \sum_s g(s) \). The real part of the increment of the scattering factor is due to the binding of electrons. \( f' \) is the dispersion component of the anomalous scattering.

If \( w \) is comparable to \( w_s \), but slightly greater, \( ikw \) must not be neglected, \( f \) becomes complex (Equation 80):

\[ f = f' + if'' = f_0 + \Delta f' + i\Delta f'' \]  

(80)

The imaginary part lags \( \pi/2 \) behind the primary wave, i.e. is always \( \pi/2 \) in front of the scattered wave. \( \Delta f'' \) is known as the absorption component of the anomalous scattering.

In the quantum mechanical treatment of the problem the oscillator strengths are calculated from the atomic wave functions. Hönöl,\(^{42}\) in theoretical work, used hydrogen-like atomic wave functions. In the frame of this approach, to each natural dipole frequency \( w_s \) in the classical expression there corresponds in the quantum expression a frequency \( w_{kn} \), which is the Bohr frequency associated with the transition of the atom from the energy state \( k \) to the state \( n \) in which it is supposed to remain during the scattering. Modern quantum mechanical calculations of anomalous scattering factors on isolated atoms, based on relativistic Dirac–Slater wave functions, have been carried out by Cromer and Liberman.\(^{43}\) It follows from the theory of the anomalous scattering of X-rays that \( f_0 \) is real, independent of the wavelength of the incident X-rays but dependent on the scattering angle. \( \Delta f' \) and \( \Delta f'' \) depend on the wavelength, \( \lambda \), of the incident radiation but are virtually independent of the scattering angle.

4.2.2 Experimental Determination

\( \Delta f'' \) is related to the atomic absorption coefficient \( \mu_0 \) by Equation (81):

\[ \Delta f''(w) = \frac{mcw}{4\pi} \mu(w_0) \]  

(81)

\( \Delta f' \) can now be calculated by the Kramers–Kronig transformation (Equation 82):

\[ \Delta f'(w) = \frac{2}{\pi} \int_0^\infty \frac{w'\Delta f''(w')}{w^2 - w'^2} \, dw' \]  

(82)

As fluorescence is closely related to absorption, fluorescence measurements varying the X-ray radiation frequency are used to determine the frequency dependence of the dispersive components of the different chemical elements. Instead of the radiation frequency \( w \), the radiation is often characterized by its wavelength, \( \lambda \), or photon energy, \( E \). The dispersion correction terms \( \Delta f' \) and \( \Delta f'' \) are often simply denoted \( f' \) and \( f'' \).

Figure 30 shows the anomalous scattering factors near the absorption K edge of selenium from a crystal of \( E. coli \) selenomethionyl thioredoxin. The spectrum was measured with tunable synchrotron radiation. Apart from the “white line” feature at the absorption edge, \( f'' \) drops by about 4 electrons approaching the edge from the short wavelength side; \( f'' \) exhibits a symmetrical drop of \(-8\) electrons around the edge. Similar values can be observed at the K edges for Fe, Cu, Zn and Br, whose wavelengths all lie in the range 0.9–1.8 Å, which is well suited for biological macromolecular X-ray diffraction experiments. For other interesting heavy atoms such as Sm, Ho, Yb, W, Os, Pt and Hg the L\(_{II}\) (Sm) or L\(_{III}\) edges are in this range.
Here, the effects are even greater. Considerably larger changes are found for several lanthanides, such as Yb, where the minimum \( f \) is \(-33\) electrons and the maximum \( f'' \) is 35 electrons.

### 4.2.3 Breakdown of Friedel’s Law

Under the assumption that the crystal contains a group of anomalous scatterers, one can separate the contributions from the distinctive components of the scattering factor according to Hendrickson and Ogata\(^{(43)}\) to obtain Equation (83):

\[
^4F(h) = \^N_0F(h) + ^A_0F(h) + ^A_0F(h) + ^A_0F(h)
\]

where \( ^N_0F(h) \) is the contribution of the normal scatterers and \( ^A_0F(h) \) and \( ^A_0F(h) \) are the contributions for the corresponding components of the complex atomic form factor. For the centrosymmetric reflection we obtain Equation (84):

\[
^4F(-h) = \^N_0F(-h) + ^A_0F(-h) + ^A_0F(-h) + ^A_0F(-h)
\]

The geometric presentation for both structure factors is given in Figure 31. The inversion of the sign of \( h \) causes a phase angle for all contributions where the components of the scattering factor are real. For the \( f'' \)-dependent part this is also valid but owing to the imaginary factor \( i \) this vector has to be constructed with a phase angle \(+\pi/2\) with respect to \( ^A_0F(-h) \) and \( ^A_0F(-h) \).

### 4.2.4 Anomalous Difference Patterson Map

One can show that (Equation 85)

\[
^4F(h) - ^4F(-h) \approx \frac{2}{k}[^A_0F(h) + ^A_0F(h)] \sin(\alpha_h - \alpha_A)
\]

where \( \alpha_h \) is the phase angle of \( ^4F(h) \), \( \alpha_A \) the phase angle of the anomalous scatterers and (Equation 86)

\[
k = \frac{^A_0F(h) + ^A_0F(h)}{^A_0F(h)}
\]

As coefficients for an anomalous difference Patterson we obtain Equation (87):

\[
\Delta F_{ano}^2 = [^4F(h) - ^4F(-h)]^2
\sim \frac{4}{k^2}[^A_0F(h) + ^A_0F(h)]^2 \sin^2(\alpha_h - \alpha_A)
\]

The \( \Delta F_{ano} \)s will be maxima if the phase angle \( \alpha_A \) is perpendicular to the phase angle \( \alpha_h \) and zero if both vectors are collinear, which is opposite to the MIR case. The anomalous Patterson map contains peaks of the anomalous scatterers with heights proportional to half of \( (4/k^2) \[ ^A_0F(h) + ^A_0F(h) \]^2 \) owing to the \( \sin^2 \) term and is therefore suited to determine the structure of the anomalous scatterers.
4.2.5 Phasing Including Anomalous Scattering Information

The combination of anomalous scattering information with isomorphous replacement permits the unequivocal determination of the protein phases as shown in Figure 32. Using the anomalous scattering information alone gives two possible solutions for the protein phase characterized by the intersection points H and L in Figure 32. Combining it with the corresponding intensities from isomorphous heavy atom derivatives, each with anomalous scattering contributions, the Harker construction can be extended for this situation and the phasing method is then designated multiple isomorphous replacement anomalous scattering (MIRAS).

4.2.6 Multiwavelength Anomalous Diffraction Technique

During the last few years, the MAD technique has matured to be a routine method and led to a revolution in biological macromolecular crystallography. If there are one or a few anomalous scatterers in the biological macromolecule it is possible to determine the whole spatial structure from one crystal (exact isomorphism) by the MAD technique. The anomalous scatterers may be intrinsic as in metalloproteins (e.g. Fe, Zn, Cu, Mo, Mn) or exogenous (e.g. Hg in a heavy atom derivative or Se in selenomethionyl proteins\(^{45,46}\)). A prerequisite for the MAD technique is well diffracting crystals (resolution better than 2.8 Å) because the anomalous components of the atomic form factor are virtually independent of the diffraction angle and acquire increasing weight with increasing scattering angle. This advantageous property together with exact isomorphism serves for the determination of good phases down to the full resolution and leads to the production of excellent experimental MAD-phased electron density maps. A typical MAD experiment is carried out at three different wavelengths (tunable synchrotron radiation), at minimum \(f'\) and maximum \(f''\) at the absorption edge of the anomalous scatterer(s) and at a remote wavelength where anomalous scattering effects are small.

The basic equations for the MAD technique as formulated by Hendrickson and Ogata\(^44\) are as follows. Equation (83) can be written as Equation (88):

\[
\lambda F(h) = \delta F_T(h) + \lambda F_A(h) + \delta F_A(h) \tag{88}
\]

where (Equation 89):

\[
\delta F_T = \delta F_N + \delta F_A \tag{89}
\]

with subscript \(T\) for the totality of atoms in the structure. Furthermore, we have Equations (90–93):

\[
\delta F_T f'' = \delta F_T \exp(i\phi_T) \tag{90}
\]

\[
\delta F_A f'' = \delta F_A \exp(i\phi_A) \tag{91}
\]

\[
\lambda F_A = f(f') \tag{92}
\]

\[
\delta F_A' = f(f'') \tag{93}
\]

In the common case of a single kind of anomalous scatterer Equations (94) and (95):

\[
\lambda F_A' = \frac{f'(\lambda)}{f'} \delta F_A \tag{94}
\]

\[
\delta F_A'' = \frac{f'(\lambda)}{f'} \delta F_A \tag{95}
\]

Separating the experimentally observable squared amplitude into wavelength-dependent and wavelength-independent terms gives Equation (96):

\[
\lambda F(\pm h)^2 = \delta F_N^2 + a(\lambda)^2 F_A^2 \]

\[
+ b(\lambda)^2 F_T F_A \cos(\phi_T - \phi_A) \]

\[
\pm c(\lambda)^2 F_T F_A \sin(\phi_T - \phi_A) \tag{96}
\]
with (Equations 97–99)

\[
a(\lambda) = \frac{f'^2 + f''^2}{f'^2}\tag{97}
\]

\[
b(\lambda) = 2\frac{f'}{f'^2}\tag{98}
\]

\[
c(\lambda) = 2\frac{f''}{f'^2}\tag{99}
\]

Maximum anomalous scattering effects can be expected in intensity differences of reflections that would be equal for exclusively normal scattering. This is the case for Friedel pairs, \(h\) and \(-h\), or their rotational symmetry partners and the relation for such differences is given in Equation (85). Of further interest are dispersive differences between structure amplitudes at different wavelengths Equation (100):

\[
\Delta F_{\Delta h} = \lambda F(h) - \lambda F(h)\tag{100}
\]

The anomalous or dispersive intensity differences can be used to determine the structure of the anomalous scatterers. The methods are the same as for isomorphous replacement. They include vector verification procedures of difference Patterson maps or direct methods.

4.2.7 Determination of the Absolute Configuration

As anomalous scattering destroys the centrosymmetry of the diffraction data, this effect can be used to determine the absolute configuration of chiral biological molecules. The most common method is to calculate protein phases based on both hands of the heavy atom or anomalous scatterer structures and check the quality of the relevant electron density map which should be better for the correct hand. Furthermore, secondary structural elements in proteins (consisting of L-amino acids) such as \(\alpha\)-helices should be right-handed.

4.3 Patterson Search Methods (Molecular Replacement)

If the structures of molecules are similar (virtually identical) or contain a major similar part, this can be used to determine the crystal structure of the related molecule if the structure of the other molecule is known. This is done by systematically exploring the Patterson function of the crystal structure to be determined with the Patterson function of the search model. Let us first consider some important features of the Patterson function. The relation between two identical molecules in the search crystal structure (Figure 33a) can generally be formulated as Equation (101):

\[
X_2 = [C]X_1 + d\tag{101}
\]

Equivalent positions \(X_1\) in molecule 1 are at positions \(X_2\) of molecule 2. \([C]\) is the rotation matrix and \(d\) the translation vector of the movement of the molecule. Figure 33(b) shows the Patterson function belonging to the molecular arrangement in Figure 33(a). It is evident that around the origin vectors are assembled that are intramolecular whereas the vectors around lines AB and EF are intermolecular. The intramolecular vectors depend on the molecule orientation only and therefore can be used for its determination. Once the orientation of the molecule(s) has been elucidated this can be used to reveal the translation of the molecule(s) by analyzing the intermolecular vector part of the Patterson function. The distinction between intra- and intermolecular vector sets and exploiting them for orientation and translation determination was given by Hoppe. \(^{47}\) The extension to protein crystallography and the first mathematical formulation of the rotation and translation functions were given by Rossman and Blow. \(^{48}\)

4.3.1 Rotation Function

The intramolecular vectors are arranged in a volume around the origin of the Patterson function with a radius equal to the dimension of the molecule. The rotational search is then carried out in this volume \(n\). The search Patterson (deduced either from the search model or from the crystal Patterson itself) is rotated to any possible rotational orientation \(X_2\) characterized by three
rotational angles $\alpha, \beta, \gamma$ which may be defined in different ways (polar angles, Eulerian angles, etc.). At each angular position the actual functional values are correlated with those of the crystal Patterson all through the volume $u$ and integrated over this volume. The correlation function may be the sum or the product of each corresponding pair of values. Rossmann and Blow proposed a product function and the rotation function for this case is given by Equation (102):

$$R(\alpha, \beta, \gamma) = \int P_2(X_2)P_1(X_1)\,dX_1 \tag{102}$$

The function has maxima if the intramolecular vector sets are coincident. The calculation can be carried out in both direct and reciprocal space.

The self-rotation function is a special form of the rotation function. If an asymmetric unit contains more than one copy of a molecule, the rotation matrix between the molecules can be determined by a self-rotation function. Here, the crystal Patterson is rotated against itself and the integration is taken over the volume $u$ around the origin in the same manner. The identical molecules may have an arbitrary orientation to each other or they may be related by local or so-called noncrystallographic symmetries. Searching for local rotation axes is done best in a polar angle system. The search Patterson is brought into each polar orientation and then rotated around the angle value for the local axis being sought, e.g. $120^\circ$ for a threefold local axis.

4.3.2 Translation Function

Once the orientation of the molecule(s) has been determined, the translation of the molecule(s) can be obtained from a translation function. The model Patterson $P_2(u)$ revealed from the model in the correct orientation is calculated for different translations $t$ and correlated with the crystal Patterson $P_1(u)$. The translation function proposed by Crowther and Blow has the form shown in Equation (103):

$$T(t) = \int P_1(u)P_2(u, t)\,du \tag{103}$$

$T(t)$ reveals a maximum peak at the correct translation $t$ if the center of gravity of the search model was at the origin for $t = 0$.

4.3.3 Computer Programs for Molecular Replacement

An early program for molecular replacement, working in direct space, was written by Huber. Nowadays, several program packages are available, either being exclusively dedicated to the molecular replacement technique or having integrated relevant modules. Pure molecular replacement programs are e.g. AMORE and GLRF. The rotational and translational search starting from the search model is fully automated in AMORE and includes a final rigid body refinement of each proposed solution. GLRF offers different types of rotation and translation functions, all operating in reciprocal space, and a Patterson correlation refinement. A peculiarity of the GLRF program is the locked rotation function. This function takes into account possible noncrystallographic symmetries and is an average of $n$ independent rotation functions with an improved peak-to-noise ratio. Frequently used program packages including molecular-replacement modules are the CCP4 program suite, X-PLOR and PROTEIN.

4.4 Phase Calculation

4.4.1 Refinement of Heavy Atom Parameters

Before the protein phases can be calculated, it is necessary to refine the heavy atom parameters. These are the coordinates $x, y, z$, the temperature factor (either isotropic or anisotropic) and the occupancy. The refinement modifies the parameters in such a way that $|\langle F_{PH}(obs) \rangle|$ becomes as close as possible to $|\langle F_{PH}(calc) \rangle|$. Using the method of least squares, the refinement according to Rossmann minimizes Equation (104):

$$\varepsilon = \sum_k w(h)[(F_{PH} - F_H)^2 - kF_{Heal}^2] \tag{104}$$

where $k$ is a scaling factor to correct $F_{Heal}^2$ to a theoretically more acceptable value because according to Equation (64) $F_{PH} - F_P$ and $F_H$ have approximately the same length when $F_{PH}$, $F_P$ and $F_H$ point in the same direction. The probability for this case will be high if the difference between $F_{PH}$ and $F_P$ is large. An improvement can be obtained if the contribution from the anomalous scattering is included.

For the parameter refinement of anomalous scattering sites, the differences between the observed and calculated structure factor amplitudes for $\sigma F_{\chi}$ are subjected to minimization. Another approach treats the anomalous or dispersive contributions as in MIR phasing.

From the refined heavy atom parameters, preliminary protein phase angles $\alpha_p$ can be obtained as shown in the corresponding Harker construction. A further refinement of the heavy atom parameters can be achieved by the “lack of closure” method incorporating this knowledge. The definition of this “lack of closure” $\varepsilon$ is illustrated in Figure 34(a) and (b). In the case of perfect isomorphism, the vector triangle $F_P + F_H = F_{PH}$ closes exactly (Figure 34a). In practice, this condition will not be fulfilled and a difference $\varepsilon$ between the observed $F_{PH}$...
and the calculated \( F_{PH} \) will remain (Figure 34b). \( F_{PH}(\text{calc}) \) can be obtained from the triangle OAB (Figure 34b) with the cosine rule (Equation 105):

\[
F_{PH} = \left[ F_P^2 + F_H^2 + 2F_P \times F_H \cos(\alpha_H - \alpha_P) \right]^{1/2}
\]  

(105)

The function which is minimized by the least-squares method is Equation (106):

\[
E_j = \sum_{h} m_h e_j(h)^2
\]  

(106)

where (Equation 107)

\[
e_j = k_j F_{PH,\text{obs}} - F_{PH,\text{calc}}
\]  

(107)

is the “lack of closure” for the heavy atom derivative \( j \), \( k_j \) is a scaling factor and \( m_h \) is a weighting factor.

---

### 4.4.2 Protein Phases

As the structure factor amplitudes \( F_P, F_{PH}, F_H \) and \( \alpha_H \) are known, the protein phase angle \( \alpha_P \) can be calculated. For the single isomorphous replacement situation (Figure 27) \( \varepsilon \) is zero only for the two protein phase angles \( \alpha_P \) where the two circles for \( F_P \) and \( F_{PH} \) intersect. In practice, all these observed quantities exhibit errors. For the treatment of these errors it is assumed that all errors are in \( F_{PH} \) and that both \( F_H \) and \( F_P \) are error-free. For each protein phase angle \( \alpha \), \( \varepsilon(\alpha) \) is calculated. The smaller \( \varepsilon(\alpha) \) is, the higher is the probability of a correct phase angle \( \alpha \). For each reflection of a derivative \( j \) a Gaussian probability distribution is assumed for \( \varepsilon \) according to Equation (108):

\[
P(\alpha) = P(\varepsilon) = N \exp\left( -\frac{\varepsilon^2(\alpha)}{2E^2} \right)
\]  

(108)

where \( N \) is a normalization factor and \( E^2 \) the mean square value of \( \varepsilon \). Small values of \( E \) are related to probability curves with sharp peaks and well-determined phase angles and the opposite is true for large \( E \) values.
Such phase-angle probability curves can be calculated for each individual reflection and derivative. For single isomorphous replacement this curve is symmetric with two high peaks corresponding to the two possible solutions for \( \alpha_p \). We obtain the total probability for each reflection with contributions from \( n \) heavy atom derivatives by multiplying the individual probabilities (Equation (109)):

\[
P(\alpha) = \prod_{j=1}^{n} P_j(\alpha) = N' \exp - \sum_j \frac{\varepsilon_j^2(\alpha)}{2E_j^2} \tag{109}
\]

These curves will be nonsymmetric with one or several maxima (see Figure 35a and b).

The question arises of which phases should be taken in the electron density equation to calculate the best electron density. An immediate guess would be to use the electron density equation to calculate the best electron maxima (see Figure 35a and b). These curves will be nonsymmetric with one or several maxima for bimodal distributions. Blow and Crick would be appropriate for unimodal distributions but not for bimodal distributions. Blow and Crick (59) derived the phase value that must be applied under the assumption that the mean square error in electron density over the unit cell is minimal. For one reflection this is given by Equation (110):

\[
\langle \Delta \rho^2 \rangle = \frac{1}{V^2} (F_i - F_t)^2 \tag{110}
\]

where \( F_i \) is the true and \( F_t \) the structure factor applied in the Fourier synthesis. The mean square error is then obtained as Equation (111):

\[
\langle \Delta \rho^2 \rangle = \frac{1}{V^2} \int_{-\pi}^{\pi} \left( F_i - F \exp(ia) \right)^2 P(\alpha) \, d\alpha \int_{-\pi}^{\pi} P(\alpha) \, d\alpha \tag{111}
\]

\( F_t \) has a phase probability of \( P(\alpha) \) and has been given as \( F_i = F \exp(ia) \). It can be shown that the numerator integral in Equation (111) is minimal if (Equation (112)):

\[
F_{s(best)} = \frac{\int_{-\pi}^{\pi} \exp(ia) P(\alpha) \, d\alpha}{\int_{-\pi}^{\pi} P(\alpha) \, d\alpha} = mF \exp(ia_{best}) \tag{112}
\]

Equation (112) corresponds to the center of gravity of the probability distribution with polar coordinates \( (mF, a_{best}) \), where \( m \) is defined as magnitude of \( m \) given by Equation (113):

\[
m = \frac{\int_{-\pi}^{\pi} P(\alpha) \exp(ia) \, d\alpha}{\int_{-\pi}^{\pi} P(\alpha) \, d\alpha} \tag{113}
\]

This magnitude of \( m \) is equivalent to a weighting function and is designated the “figure of merit”. The electron density map calculated with \( mF \) and \( a_{best} \) is known as “best Fourier” and should represent a Fourier map with minimum least-squares error from the true Fourier map.

For the total error of the “best Fourier”, Equation (114) has been derived:

\[
\langle \Delta \rho^2 \rangle = \frac{1}{V^2} \sum_{h} F^2(h)(1 - m^2) \tag{114}
\]

The order of magnitude of this error may be illustrated by the example of the structure determination of lysozyme. The root mean square error in the Fourier synthesis was 0.35 e\( \text{Å}^{-3} \) with values of 2.0 Å resolution for the diffraction data and a mean “figure of merit” of 0.6.

The program systems CCP4(36) and PROTEIN(55) contain all routines necessary to calculate protein phases according to the MIRAS technique and a number of different kinds of Fourier maps. Alternative probabilistic approaches for the phase calculation are used in programs MLPHARE(60) and SHARP(61). Both programs can also carry out MAD phasing. The MADSYS program (62) is based on the algebraic approach outlined in the MAD section of this contribution and executes all tasks of a MAD analysis from scaling to phase-angle calculation.

### 4.5 Phase Improvement

With the methods so far described an experimental electron density map can be calculated and if its quality is high enough the atomic model can be constructed. However, there are methods for further phase improvement available which may be applied in general or depending on given prerequisites. Such phase improvement routines have been used routinely over the last 10 years and have had a large impact on the advancement of biological macromolecular crystallography.

#### 4.5.1 Solvent Flattening

Protein crystals have a solvent content of 75–40%. In a highly refined protein crystal structure the solvent space between the molecules is rather flat owing to the dynamic nature of this region. Usually the initial experimental starting phases are of lower quality than the final ones and as a result the solvent region (if the molecular boundaries can be identified) contains noise peaks. It is now obvious to set the noisy solvent space to a low constant value and calculate new improved phases by Fourier back-transforming this corrected electron density map. However, it is evident that the definition of the molecular boundaries will be tedious and depend on the quality of the electron density map. Wang(63)
has proposed an automatic procedure which smooths the electron density to define the protein region. This smoothed electron density map is traced against a threshold value which separates this map into molecule and solvent space according to their ratio of volumes in the unit cell. The space inside the molecular envelope is polished to avoid internal voids. Now, a new electron density map is calculated using the observed structure factor amplitudes and the phases revealed from the solvent corrected map. The solvent corrected map is obtained by setting all electron density values inside the molecular envelope to those of the initial map and all values outside the envelope to a low constant value. These phases from the solvent flattening procedure can be combined with the MIR or MAD phases. This procedure can be repeated in several iterative cycles because after each cycle of solvent flattening the quality of the electron density map is improved. There are no prerequisites for the application of the method of solvent flattening. It is evident that solvent flattening is most effective for crystals with a high solvent content.

4.5.3 Molecular Averaging

If there is more than one identical subunit in the asymmetric unit of the crystal, molecular averaging can be used to improve the protein phases. The spatial relations between the single identical subunits in the asymmetric unit may be determined by Patterson search methods or from the arrangement of the heavy atoms or anomalous scatterers. The spatial relation between the identical subunits can be improper (the relevant spatial movement consists of a rotation about an unsymmetrical angle value and a translation component) or proper (the spatial movements form a symmetry group which is composed of rotational symmetry elements only). Such additional symmetries are called noncrystallographic or local and there are no limitations concerning the Zähligkeit of the symmetry axes (e.g. five-, seven- and higher-fold axes are allowed). It is evident that averaging about the different related subunits, whose electron density should be equal in each subunit, must result in an improved electron density map and therefore in improved protein phases. Molecular averaging is best done in direct space and several programs (e.g. RAVE\(^{65}\) or MAIN\(^{66}\)) are available.

The procedure of molecular averaging is composed of several steps. First, the molecular envelope must be determined from the initial electron density map or from a molecular model which, for example, has been obtained from molecular replacement. Next, the particular electron density averaging between the related subunits is performed. This is followed by the reconstitution of the complete crystal unit cell with the averaged electron density. The space outside the molecular envelope is flattened. This map is then Fourier back-transformed. The obtained phase angles can either be taken directly or combined with known phase information to calculate a new and improved electron density map. This cycle can be repeated several times until convergence of the electron density map improvement has been reached. It is very useful to refine the local symmetry operations after every macrocycle of molecular averaging. Furthermore, molecular averaging can be applied if proteins crystallize in more than one crystal form.

Molecular averaging is especially efficient if a high noncrystallographic symmetry is present as in virus structures, but the averaging over two related subunits alone (the lowest case of local symmetry) can give a considerable improvement. In special cases where high noncrystallographic symmetry exists and the phase information extends to low resolution only, cyclic molecular averaging can be used to extend the phase angles to the full resolution of the native protein. This was first shown in the structure analysis of hemocyanin from Panulirus interruptus.\(^{67,68}\) It is extensively used in the analysis of icosahedral structures (see, e.g. Rossmann et al.\(^{69}\) and Ladenstein et al.\(^{70}\)) and for large molecular assemblies (e.g. Löwe et al.).\(^{71}\)

4.5.4 Phase Combination

In the course of a crystal structure analysis of a biological macromolecule, phase information from different sources may be available, such as information from isomorphous replacement, anomalous scattering, partial structures, solvent flattening and molecular averaging. An overall phase improvement can be expected when these factors are combined and a useful method to do this was proposed by Hendrickson and Lattman.\(^{72}\) The probability curve
for each reflection is written in an exponential form as Equation (115):

\[
P_s(\alpha) = N_s \exp(K_s + A_s \cos \alpha + B_s \sin \alpha + C_s \cos 2\alpha + D_s \sin 2\alpha)
\]

(115)

Subscript \( s \) stands for the source from which the phase information has been derived. \( K_s \) and the coefficients \( A_s, B_s, C_s \) and \( D_s \) depend on the structure factor amplitudes and other magnitudes, e.g. the estimated standard deviation of the errors in the derivative intensity, but are independent of the protein phase angles \( \alpha \). The overall probability function \( P(\alpha) \) is obtained by a multiplication of the individual phase probabilities and this turns out to be a simple addition of all \( K_s \) and of the related coefficients in the exponential term. We obtain Equation (116):

\[
P(\alpha) = \prod_s P_s(\alpha)
\]

\[
= N' \exp \left( \sum_s K_s + \left( \sum_s A_s \cos \alpha + \sum_s B_s \sin \alpha \right.ight.

\[
+ \left. \left( \sum_s C_s \cos 2\alpha + \sum_s D_s \sin 2\alpha \right) \right)
\]

(116)

\( K_s \) and the coefficients \( A_s - D_s \) have special expressions for each source of phase information and they are explicitly given e.g. in Drenth.(21)

### 4.6 Difference Fourier Technique

Supposing that one has solved the crystal structure of a biological macromolecule and has isomorphous crystals of this macromolecule which contain small structural changes caused by a substrate-analog or inhibitor binding, a metal removal or replacement or a local mutation of one or several amino acids. Then these structural changes can be determined by the difference Fourier technique. The difference Fourier map is calculated with the differences between the observed structure factor amplitudes of the slightly altered molecule \( F_{\text{DERI(obs)}} \) and the native molecule \( F_{\text{NATI(obs)}} \) as Fourier coefficients and the phase angles of the native molecule \( \alpha_{\text{NATI}} \) as phases according to Equation (117):

\[
\rho_{\text{DERI}} - \rho_{\text{NATI}} \simeq \frac{1}{V} \sum_h m[F_{\text{DERI(obs)}} - F_{\text{NATI(obs)}}] \times \exp(i\alpha_{\text{NATI}}) \exp(-2\pi ihx)
\]

(117)

where \( m \) may be the figure of merit or another weighting scheme. The difference Fourier map can alternatively be calculated with coefficients \( F_{\text{DERI(calc)}} - F_{\text{DERI(calc)}} \) and phases \( \alpha_{\text{DERI(calc)}} \). \( F_{\text{DERI(calc)}} \) and \( \alpha_{\text{DERI(calc)}} \) do not include the unknown contribution of the structural change.

Figure 36(a) and (b) illustrate the relation for the structure factors involved in the difference Fourier technique. We assume that the structural change is small. If \( F_{\text{NATI}} \) is large, the structure factor amplitude of the structural change \( F_{\text{SC}} \) will be small compared with \( F_{\text{NATI}} \), and \( \alpha_{\text{DERI}} \) will be close to \( \alpha_{\text{NATI}} \). This is no longer valid if \( F_{\text{NATI}} \) is small. Now \( F_{\text{SC}} \) is comparable to \( F_{\text{NATI}} \), and \( \alpha_{\text{DERI}} \) may deviate considerably from \( \alpha_{\text{NATI}} \). This implies the necessity to introduce a weighting scheme that scales down the contributions where the probability is high that \( \alpha_{\text{NATI}} \) differs appreciable from the correct phase angle. Various weighting schemes have been elaborated such as those of Sim(73) and Read.(74) The weighting scheme of Sim has the following form (Equation 118):

\[
w = \frac{l_1(X)}{l_0(X)}
\]

(118)
for acentric reflections and (Equation 119):

\[ w = \tanh \frac{X}{2} \tag{119} \]

for centric reflection with (Equation 120)

\[ X = \frac{2F_{\text{DERI}} \times F_{\text{NATI}}}{\sum_{j} f_j^2} \tag{120} \]

$I_0(X)$ and $I_1(X)$ are modified Bessel functions of zeroth and first order, respectively. These equations and weighting schemes can also be used for the calculation of OMIT maps (where parts of the model have been omitted from the structure factor evaluation) or when a complete structure must be developed from a known partial model. $F_{\text{DERI}}$ must be replaced by the observed structure factor $F$. $F_{\text{NATI}}$ by the structure factor of the known or included part of the model $F_K$ and $\alpha_{\text{NATI}}$ by the phase angle $\alpha_K$ of the known or included part of the model.

5 MODEL BUILDING AND REFINEMENT

5.1 Model Building

Once the quality of the MIRAS or MAD maps is good enough, model building can be started. This is done on a computer graphics system and the main modeling programs are O \(^{75}\) and TURBO-FRODO \(^{76,77}\). An interesting alternative is the program MAIN \(^{66}\), which additionally contains routines for molecular averaging, molecular docking and other features. The visualization of the relevant electron density map on the computer graphics system is done as cage-like structures. For this purpose, the standard deviation from the mean value of the map is calculated and the cage-like structure is built up for a given contour level (normally 1.0 $\sigma$). The first task in a de novo protein crystal structure analysis is to localize the trace of the polypeptide chain. This can be assisted by routines for automatic chain tracing such as the bones routine, an auxiliary program of O. Such automatic chain-tracing programs generate a skeleton of the electron density map. This representation was introduced by Greer \(^{78}\). When the trace of the polypeptide chain has been identified, the atomic model can be built into the electron density. The atomic model is represented as sticks connecting the atomic centers of bonded atoms. The individual building blocks (amino acids) of the protein molecule can be generated, interactively manipulated (e.g. linked with each other, moved, rotated, etc.) and fitted into the corresponding part of the electron density map. The geometry of the atomic model is regularized according to protein standard geometries.

The success of model building depends on the quality and resolution of the experimental electron density map. Usually, the quality of the electron density map is not so good that the complete model can be constructed in one cycle. In this case, the partial atomic model is refined crystallographically against the observed structure factor amplitudes. This phase information can be used directly to calculate a new electron density map commonly with $2F_{\text{obs}} - F_{\text{calc}}$ Fourier coefficient amplitudes. This kind of map is the sum of a normal $F_{\text{obs}}$ Fourier and a difference Fourier synthesis. It displays the atomic model with normal weight and indicates errors in the model by its contribution of the difference Fourier map. The parallel determination and inspection of a difference Fourier map is also very helpful. As already mentioned, the model phases can be combined with phases present from other sources or incorporated in procedures of phase improvement. A further model-building cycle can be started with such new and improved electron density maps. After several cycles of model building and crystallographic refinement the atomic model will be so well defined that the solvent structure of internally bound solvent molecules can be developed. The atomic model is complete now and the biochemical interpretation can be started.

5.2 Crystallographic Refinement

The structural model has to be subjected to a refinement procedure. In practical macromolecular crystallography, one does not always have atomic resolution. Therefore, the single atoms cannot be treated as moving independently. They must be refined using energy or stereochemistry restraints, taking care to maintain a reasonable stereochemistry of the macromolecule.

There exist different approaches to structure refinement of macromolecules. The minimization of a potential energy function $E$ together with a diffraction term $D$ according to Equation (121):

\[ S = E + D \tag{121} \]

where (Equations 122 and 123):

\[
\begin{align*}
E &= \sum_k k_b [b_{ij}^{(\text{calc})} - b_{ij}^{(0)}]^2 + \sum_k k_t \left[ \tau_{ij}^{(\text{calc})} - \tau_{ij}^{(0)} \right]^2 \\
&\quad + \sum k_{\text{es}} [1 + \cos(m\Theta_k + \delta)] + \sum (Ar^{-12} + Br^{-6}) \\
D &= \sum_i w_i [F_{i,\text{obs}} - kF_{i,\text{calc}}]^2 
\end{align*} \tag{122, 123} \]

is applied in the programs EREF \(^{79}\) and XPLOR \(^{54}\), which is now used frequently. The four terms of the right-hand side of $E$ describe bond, valence angle, dihedral torsion angle and non-bonded interactions, $k_b$.
is the bond stretching constant, \( k_r \) is the bond angle bending force constant, \( k_{\theta} \) is the torsional barrier, \( m \) and \( \delta \) are the periodicity and the phase of the barrier, \( A \) and \( B \) are the repulsive and long-range nonbonded parameters, \( D \) is the crystallographic contribution with \( w_j \) a weighting factor, \( F_{\text{obs}} \) the observed structure factor, \( F_{\text{calc}} \) the calculated structure factor and \( k \) a scaling factor. Programs TNT\(^{80}\) and PROLSQ\(^{81}\) use stereochemically restrained least-squares refinement. For both refinement schemes parameters are employed which were derived from small molecule crystal structures of amino acids, small peptides, nucleic acids, sugars, fatty acids, cofactors etc.\(^{82}\) If noncrystallographic symmetry is present a corresponding term may be introduced in the energy or stereochemistry part of the expression to be minimized. It is possible to divide the structural model into several individual parts and refine these parts as rigid bodies. This is especially useful with solutions from molecular replacement.

A measure of the quality of the crystallographic model is calculated from the crystallographic R-factor (Equation 124):

\[
R = \frac{\sum_i |F_{\text{obs}}| - k|F_{\text{calc}}|}{\sum_i |F_{\text{obs}}|} \tag{124}
\]

Typical R-factors are below 0.2 for a well-refined macromolecular structure.

Beside the atomic coordinates \( x, y, z \), the atomic temperature factor \( B \) may be refined at a resolution better than 3.5 Å. This is done in most programs in a separate step where e.g. in program XPLOR\(^{54}\) the target function (Equation 125):

\[
T = E_{\text{XRAY}} + E_R
\]

is minimized, where (Equation 126)

\[
E_R = W_B \sum_{(i,j)\text{-bonds}} \frac{(B_{i} - B_{j})^2}{\sigma_{\text{Bonds}}} + W_B \sum_{(i,j,k)\text{-angles}} \frac{(B_i - B_k)^2}{\sigma_{\text{Angles}}} + W_B \sum_{\text{\ell\text{-group \text{j}-equivalences \text{i-unique atoms}}} \frac{(B_{ijk} - \overline{B}_{ijk})^2}{\sigma_{\text{NCS}}} \tag{126}
\]

The last term is used only if noncrystallographic symmetry restraints should be imposed on the molecules. Normally isotropic \( B \)-factors are applied and refined in macromolecular crystallography only. Even for a high-resolution structure (1.7 Å), the ratio of observations (observed structure factors) to parameters to be refined \((x, y, z, B \text{ for each atom})\) is only about 3. Therefore, as many as possible additional “observations” (energy or stereochemistry restraints) are incorporated. In some cases it is useful to refine the individual occupancy of certain atoms such as bound metal ions or solvent atoms. This must be performed in a separate step.

All of the mentioned refinement procedures are based on the least-squares method. The radius of convergence for this method is not very high because it follows a downhill path to its minimum. If the model is too far away from the correct solution, the minimization may end in a local minimum corresponding to an incorrect structure. Brünger\(^{83,84}\) introduced the method of molecular dynamics (MD) which is able to overcome barriers in the S-function and find the correct global minimum. MD calculations simulate the dynamic behavior of a system of particles. The basic idea of the MD refinement technique is to increase the temperature sufficiently high for the atoms to overcome energy barriers and then to cool slowly to approach the energy minimum. This MD protocol is designated as simulated annealing (SA). The crystallographic application of the MD or SA technique includes a crystallographic term \( D \) as given in Equation (121) treated as a pseudoenergy term. A crystallographic MD or SA refinement is capable e.g. of overcoming a high-energy barrier occurring in the flipping of a peptide plane. It can be useful in removing model bias from the system.

A new approach is the refinement of macromolecular structures by the maximum likelihood method. Programs working on the basis of this method are REFMAC\(^{85}\) and CNS\(^{86}\). The results derived using the maximum likelihood residual are consistently better than those from least-squares refinement.

If the resolution of a biological macromolecular crystal structure is equal to or better than 1.2 Å it is in the range of real atomic resolution and the ratio of observations to parameters is high enough to carry out, in principle, an unrestrained crystallographic refinement. Advances in cryogenic techniques, area detectors and the use of synchrotron radiation enabled macromolecular data to be collected to atomic resolution for an increasing number of proteins.\(^{87}\) SHELXL\(^{88}\) is a program with all tools for the crystallographic refinement of biological macromolecules at real atomic resolution.

### 5.3 Accuracy and Verification of Structure Determination

A measure of the quality of a structure determination is the crystallographic R-factor given in Equation (124). For a high-resolution structure, e.g. 1.6 Å, it should not be much larger than 0.16. As this R-factor is an overall number, it does not indicate major local errors. This can be obtained by the evaluation of a real space R-factor\(^{75}\) which is calculated on a grid for nonzero
elements according to Equation (127):

\[
R_{\text{real space}} = \frac{\sum |\rho_{\text{obs}} - \rho_{\text{calc}}|}{\sum |\rho_{\text{obs}} + \rho_{\text{calc}}|}
\]  

(127)

where \(\rho_{\text{obs}}\) is the observed and \(\rho_{\text{calc}}\) the calculated electron density.

It has been shown that the conventional \(R\)-factor may reach rather low values in a crystallographic refinement with structural models that turned out to be wrong later. To overcome this unsatisfactory situation, Brünger\(^{89,90}\) proposed the additional calculation of a so-called free \(R\)-factor. For this purpose the reflections are divided into a working set (e.g. 90\%) and a test set (e.g. 10\%). The reflections in the working set are used in the crystallographic refinement. The free \(R\)-factor is calculated with reflections from the test set which were not used for the crystallographic refinement and is thus unbiased by the refinement process. There exists a high correlation between the free \(R\)-factor and the accuracy of the atomic model phases.

The accuracy of the final model expressed by the mean coordinate error can be determined alternatively by a Luzzati\(^{91}\) or \(\sigma_A\) plot.\(^{74,92}\) The mean coordinate error for a macromolecular structure determined with a resolution of 2.0 Å and a crystallographic \(R\)-factor of 0.2 is in the region of ±0.2 Å.

The stereochemistry of the final model must also be checked. The root-mean-square deviation of bond lengths and bond angles from ideal geometry should not be greater than 0.015 Å and 3.0°, respectively. The conformation of the main chain folding is verified by a Ramachandran plot.\(^{93}\) The dihedral angles \(\Phi\) and \(\Psi\) are plotted against each other for each residue. The data points should lie in the allowed regions of the plot which correspond to energetically favorable secondary structures such as \(\alpha\)-helices, \(\beta\)-sheets and defined turn structures. Exceptions are glycine residues which may occur at any position in the Ramachandran plot. Further stereochemical parameters to be checked are bond lengths and angles, dihedral angles (e.g. determinating side-chain conformations), noncovalent interactions, geometry of H-bonds and interactions in the solvent structure. This can be done with the programs PROCHECK\(^{94-96}\) or WHAT_CHECK.\(^{97}\)

Nearly all spatial structures of biological macromolecules determined either by X-ray crystallography or nuclear magnetic resonance (NMR) techniques have been and will be deposited with the Protein Data Bank\(^{98}\) at Brookhaven National Laboratory or its successor. The information of the structural model is in a file that contains for each individual atom of the model a record with atom number, atom name, residue type, residue name, coordinates \(x, y, z\), \(B\)-value(s) and occupancy. The header records hold useful information such as crystal parameters, amino acid sequence, secondary structure assignments and references.

6 APPLICATIONS

6.1 Enzyme Structure and Enzyme–Inhibitor Complex

6.1.1 X-ray Structure of Cystathionine \(\beta\)-Lyase

Cystathionine \(\beta\)-lyase (CBL) is a member of the \(\gamma\)-family of pyridoxal-5'-phosphate (PLP)-dependent enzymes that cleaves \(\text{C}^\beta=\text{S}\) bonds of a broad variety of substrates. The crystal structure of CBL from \(E. coli\) has been solved using MIR phases in combination with density modification.\(^{99}\) The enzyme has been crystallized by the hanging drop vapor diffusion method using either ammonium sulfate or PEG 400 as precipitating agent. The crystals belong to the orthorhombic space group \(C222_1\) with unit cell parameters \(a = 60.9\,\text{Å}, b = 154.7\,\text{Å}\) and \(c = 152.7\,\text{Å}\). There is one dimer per asymmetric unit. A native data set has been collected using synchrotron radiation (wavelength 1.1 Å) at the wiggler beamline BW6 at the storage ring DORIS at the Deutsches Elektronensynchrotron (DESY) in Hamburg, Germany. Data sets for three heavy atom derivatives [thiomersalate, 2-mercuri-4-diazobenzoic acid and platinum(II)-2,2'-6,6'-terpyridinium chloride] were registered on an imaging plate scanner (MAR Research, Hamburg, Germany) using graphite monochromatized Cu Ka radiation from an RU200 rotating anode generator (Rigaku, Tokyo, Japan) operating at 5.4 kW. The reflection data were processed with the MOSFLM package\(^{30}\) and scaled with programs from the CCP4 program suite.\(^{36}\) All data sets reveal satisfactory symmetry consistency factors (\(R_{\text{merge}} \leq 0.08\)) and completenesses (≥90\%). The heavy atom positions were determined from isomorphic difference Patterson maps using the vector verification routines of program PROTEIN.\(^{55}\) All derivatives have one common heavy atom binding site at Cys72 and one of the mercury derivatives shows a second binding site at Cys229. The dimer in the asymmetric unit is related by a local twofold axis which lies parallel to the \(x\)-axis. The translation of this local axis was determined from the distribution of the heavy atom sites in the unit cell. An initial MIR map was calculated, followed by solvent flattening, twofold averaging about the local symmetry and density modification and phase extension to 2.5 Å resolution. Phase calculations, solvent flattening, density modification and phase extension were done with programs of the CCP4 package. Program AVE\(^{65}\) was used for the averaging. The quality of the resulting electron density map was sufficiently high to build an
almost complete atomic model. Model building was performed on an ESV-30 Graphic system workstation (Evans and Sutherland, Salt Lake City, UT, USA) using program O. The atomic model was refined by energy restrained crystallographic refinement with XPLOR.

The final model of CBL is made up of two monomers with 391 amino acids each, one cofactor and one hydrogen carbonate molecule per monomer and 581 solvent water molecules. The final crystallographic R-factor is 0.152 for data from 8.0 to 1.83 Å resolution and the free R-factor is 0.221. The mean positional error of the atoms as estimated from a Luzzati plot is ±0.19 Å. A homotetramer with 222 symmetry is built up by crystallographic and noncrystallographic symmetry (Figure 37). Each monomer of CBL (Figure 38) can be described in terms of three spatially and functionally different domains. The N-terminal domain (residues 1–60) consists of three α-helices and one β-strand. It contributes to tetramer formation and is part of the active site of the adjacent subunit. The second domain (residues 61–256) harbors PLP and has an α/β structure with a seven-stranded β-sheet as the central part. The remaining C-terminal domain (residues 257–395), connected by a long α-helix to the PLP-binding domain, consists of four helices packed on the solvent-accessible side of an antiparallel four-stranded β-sheet. The fold of the C-terminal and the PLP-binding domain and the location of the active site are similar to aminotransferases. Most of the residues in the active site are strongly conserved among the enzymes of the transulfuration pathway. Figure 39 shows the final 2F_{obs} − F_{calc} map superimposed with the refined atomic model around the active site of CBL. The cage-like structures for the representation of the electron density correspond to a contour level of 1.2σ. The protein part (main- and side-chain atoms), the PLP cofactor and the hydrogen carbonate molecule are well defined in the electron density map.

The knowledge of the spatial structure of a given enzyme structure forms the basis for understanding its functional properties. It is now possible to design rational site-directed mutants or determine the

Figure 37 Ribbon plot of the CBL tetramer viewed along the x-axis. The monomers are colored differently. The blue- and green-colored monomers, which are related by a crystallographic axis (horizontal, in the plane of the paper), build up one catalytic active dimer, and the yellow and red ones the other. The location of the PLP-binding site is shown in a ball-and-stick presentation; MOLSCRIPT and RASTER3D. (Reproduced by permission of Academic Press, Ltd., from Clausen et al.99)
Figure 38  Stereo ribbon presentation of the CBL monomer, emphasizing secondary structure elements. $\alpha$-Helices are drawn as green spirals, $\beta$-strands as magenta arrows. PLP and PLP-binding Lys210 are shown in a ball-and-stick representation; MOLSCRIPT\textsuperscript{100} and RASTER3D.\textsuperscript{101} (Reproduced by permission of Academic Press, Ltd., from Clausen et al.\textsuperscript{99})

structures of enzyme–substrate, enzyme–substrate analog or enzyme–inhibitor complexes which will deliver invaluable information in understanding the enzyme’s functional properties.

6.1.2 Enzyme–Inhibitor Complex Structures of Cystathione $\beta$-Lyase

The enzyme–inhibitor X-ray structures of $\beta,\beta,\beta$-tri-fluoroalanine (TFA) and L-aminoethoxyvinylglycine (AVG) with CBL could be determined.\textsuperscript{99,102} In both cases, crystals of the complexes were obtained by incubating the enzyme solution with inhibitor in the millimolar range and subsequent cocrystallization. The resultant crystals were isomorphous with the native enzyme, making it possible to apply the difference Fourier technique in the structure solution. The technical details for the structure analyses are given in the relevant references [CBL/TFA\textsuperscript{99} and CBL/AVG\textsuperscript{102}]. The CBL/TFA complex structure was determined to substantiate that the $\epsilon$-amino group of the active-site Lys210 can react with the nucleophile at the active site via Michael addition, which leads to covalent labeling and inactivation of the enzyme. The final $F_{\text{obs}} - F_{\text{calc}}$ and $2F_{\text{obs}} - F_{\text{calc}}$ electron density maps for the CBL/TFA complex around the active site are displayed in Figure 40. Clear, continuous electron density between the cofactor and Lys210 can be seen in this map, indicating a covalent lysine–inactivator–PLP product. In Figure 40, the blue $F_{\text{obs}} - F_{\text{calc}}$ map reveals well-defined electron density for the bound inhibitor. This binding mode of TFA to CBL corresponds to an intermediate in the reaction of TFA with CBL.\textsuperscript{99} The structure of the inactivation product proves that Lys210 is the active-site nucleophile reacting via Michael addition with the inactivator. It must also be the residue which transfers a proton from C$\alpha$ to S$\gamma$ in the reaction with the substrates.

The CBL/AVG structure\textsuperscript{102} has been determined at 2.2 Å resolution and a crystallographic $R$-factor of 0.164.

Figure 39  Stereo plot of the electron density in the active site of CBL, superimposed with the refined model of the region around the cofactor. The $2F_{\text{obs}} - F_{\text{calc}}$ map is contoured at 1.2σ and calculated at 1.83 Å resolution. (Reproduced by permission of Academic Press, Ltd., from Clausen et al.\textsuperscript{99})
The X-ray structure shows that AVG binds to the PLP cofactor forming the external aldimine. Lys210 is no longer bound to the PLP cofactor. Figure 41 is an overlay of the atomic models of native CBL (magenta), CBL/TFA (yellow) and CBL/AVG (green). The main difference in inhibitor binding is the location of Cβ and its substituents; in the TFA complex, the inactivator is directed toward the protein interior (the A face of the cofactor), whereas in CBL/AVG, Cβ is located at the B side of the cofactor. The α-carboxylate group in CBL/AVG is located in the same position as the hydrogencarbonate in the native and the α-carboxylate group of TFA in the CBL/TFA complex. The terminal amino group of AVG is held in place mainly by interactions with the hydroxyl group of Tyr111.

The experimental determination of the external aldimine structure in the CBL/AVG complex is of high relevance because it can serve as a rational basis for modeling of substrate and inhibitor binding, leading to more effective herbicides.

6.1.3 Crystal Structure of the Thrombin–Rhodniin Complex

This complex structure is an example related to pharmaceutical research. The goal of this special application is the development of more efficient blood anticoagulants. The target enzyme is α-thrombin. This enzyme is a serine proteinase of trypsin-like specificity. α-Thrombin, the key enzyme in hemostasis and thrombosis, exhibits both enzymatic and hormone-like properties and can be both pro- and anticoagulatory [see e.g. Stubbs and Bode104]. Rhodniin is a highly specific inhibitor of thrombin isolated from the assassin bug Rhodnius prolixus. Such blood-sucking animals have developed various anticoagulation mechanisms to prevent local clotting of the victim’s blood. These natural thrombin inhibitors are polypeptides of 60–120 amino acid residues.

The crystal structure of the noncovalent complex between recombinant rhodniin and bovine α-thrombin has been determined at 2.6 Å resolution. Crystals were obtained by cocrystallization of thrombin with rhodniin in an approximately 1:1 molar ratio. The structure could be solved by molecular replacement because the spatial structure of the major constituent, bovine α-thrombin, was known. Only a diffraction data set of the complex crystal had to be collected. Rotational and translational searches for the orientation and position of the thrombin molecules in the unit cell were performed with the program AMORE.51 The rotational search showed two solutions with correlation values of 0.22 and 0.20 over 0.09 for the next highest peak. Translational search and rigid body fitting for these two solutions resulted in a correlation value of 0.54 with the two independent complex molecules in the asymmetric unit. The quality of the electron density map calculated from the thrombin phases was good enough in principle to build the model of the rhodniin molecule (noncrystallographic averaging
was also applied). The structure was refined with XPLOR to an $R$-factor of 0.189 and a free $R$-factor of 0.262. Further technical aspects of the crystal structure analysis are given in van de Locht et al.\cite{105}

Figure 42 shows the structure of the complex between thrombin and rhodniin as a ribbon plot with $\alpha$-helices represented as ribbon spirals and $\beta$-strands as arrows. The N-terminal domain binds in a substrate-like manner to the narrow active-site cleft of thrombin. The C-terminal domain, whose distorted reactive-site loop cannot adopt the canonical conformation, docks to the fibrinogen recognition exosite via extensive electrostatic interactions. The peculiarity of this complex structure is that the two KAZAL-type domains of rhodniin bind to two different sites of thrombin.

6.2 Metalloproteins

Metals bound as cofactors in proteins have a great variety of functions. They may be involved in the activation of small inorganic or organic molecules, in oxygen storage and transport, in electron transport or in...
stabilizing a transition state during enzymatic catalysis. Their role may also be solely structural. The chemistry of metals in proteins has attracted the interest of inorganic chemists and has led to the formation of the field of biological inorganic chemistry. As an example of a complex metalloprotein, the multicopper oxidase ascorbate oxidase (AO) is presented.

6.2.1 Crystal Structure of the Multicopper Enzyme Ascorbate Oxidase

The blue protein AO belongs to the group of “blue” oxidases with laccase and ceruloplasmin. These are multicopper enzymes catalyzing the four-electron reduction of molecular oxygen with concomitant one-electron oxidation of the substrate. The crystal structure of AO has been solved by the MIR technique and refined to 1.9 Å resolution. The peculiarity of this structure determination is briefly described. It consists in the utilization of the information of two different crystal forms. In both crystal forms the molecules arrange themselves as homotetramers with 222 symmetry, but in crystal form 1, one of these twofold axes is realized by a crystallographic twofold axis resulting in two subunits per asymmetric unit. In crystal form 2, one homotetramer is found per asymmetric unit. In crystal form 1, six isomorphous heavy atom derivatives could be found and interpreted. An initial MIR map was calculated, solvent flattened and averaged about the local twofold axis. For crystal form 2, no phase information was available. From the averaged uninterpreted MIR map a whole tetramer was selected and used for rotational and translational searches in crystal form 2. This was successful and provided the necessary phase information for crystal form 2 and additionally the local symmetry. Now averaging could be performed both separately in the two crystal forms and subsequently between both crystal forms. The averaged electron density was transported into both unit cells and a new macrocycle of averaging could be started. These macrocycles were used to extend the phases from 3.5 Å to the full attainable resolution. This structure analysis was the first example where a molecular replacement was carried out with an uninterpreted MIR electron density-based model.

Figure 43 Schematic representation of the monomer structure of AO. (Reproduced by permission of World Scientific Publishing Co., from A. Messerschmidt, ‘Spatial Structures of Ascorbate Oxidase, Laccase and Related Proteins’, in Multi Copper Oxidases, ed. A. Messerschmidt, World Scientific Publishing, Singapore, 1997.)
AO is a homodimeric enzyme with a molecular mass of 70 kDa and 552 amino acid residues per subunit (zucchini). The three-domain structure and the location of the mononuclear and trinuclear copper centers in the AO monomer as derived from the crystal structure are shown in Figure 43. The folding of all three domains is of a similar β-barrel type. The mononuclear copper site is located in domain 3 and the trinuclear copper species is bound between domains 1 and 3. The coordination of the mononuclear copper site is depicted in Figure 44. It has the four canonical type-1 copper ligands (His, Cys, His, Met) also found in plastocyanin and azurin. The copper is coordinated to the ND1 atoms of His445 and His512, the SG atom of the Cys507 and the SD atom of Met517 in a distorted trigonal geometry. This unusual coordination geometry confers this copper site with its blue color. The trinuclear copper site (see Figure 45) has eight histidine ligands symmetrically supplied by domains 1 and 3 and two oxygen ligands. The trinuclear copper site may be divided into a pair of copper (CU2, CU3) with six histidine ligands in a trigonal prismatic arrangement. The pair is bridged by an OH\(^-\), which leads to a strong antiferromagnetic coupling and makes this copper pair electron paramagnetic resonance silent. The remaining copper has two histidine ligands and an OH\(^-\) or H\(_2\)O ligand. A binding pocket for the reducing substrate which is complementary to an ascorbate molecule is located near the mononuclear copper site and accessible from solvent.

A broad channel providing access from the solvent to the trinuclear copper species which is the binding and reaction site for the dioxygen is present in AO. During catalysis an intramolecular electron transfer between the mononuclear copper site and the trinuclear copper cluster occurs. The distances between the mononuclear copper and the three coppers of the trinuclear center are 12.20, 12.69 and 14.87 Å, respectively. Furthermore, the crystal structures of functional derivatives of AO such as the reduced, azide and peroxide form have been determined. They show considerable changes at the trinuclear copper site in the reduced form and the peroxide or azide binding to the trinuclear copper species in the relevant structures. The X-ray studies on AO delivered essential information in understanding the catalytic mechanism.

6.2.2 Crystal Structure of Cytochrome-c\(_{552}\) from Thermus thermophilus Determined by Multiwavelength Anomalous Diffraction Phasing

The spatial structure of cytochrome-c\(_{552}\) from Thermus thermophilus has been solved by the MAD technique using synchrotron radiation and refined at a resolution of 1.28 Å to a R-factor of 0.19. The data collection for the MAD phasing was performed at the wiggler beamline BW6 at the storage ring DORIS at DESY in Hamburg, Germany. At the beginning, an X-ray fluorescence spectrum around the Fe K-absorption edge

was registered using an NaI(Tl) scintillation counter. Evaluation of the spectrum with program DISCO gave the anomalous dispersion contributions, $f'$ and $f''$, as a function of photon energy (Figure 46). Subsequently, diffraction data were collected at three different photon energies. Two of them, 7138 and 7125 eV, correspond to maximum $f''$ and minimum $f'$, respectively. The choice of the third, 10077 eV, was for scaling purposes. A fourth high-resolution data set (1.28 Å) was collected at a photon energy of 11810 eV. All data sets were obtained from a single crystal which had been shock-frozen at 90 K. Anomalous and dispersive Patterson syntheses were calculated from each of the MAD data sets. All showed strong Harker peaks from which the coordinates of the heme Fe atom (one Fe atom per asymmetric unit) could be determined easily. MAD phases were calculated with programs MADSYS and MADPRB. The resulting initial electron density map at a resolution of 2.1 Å was of high quality and allowed the construction of the complete atomic model into that map.

Cytochrome-c transports electrons between complexes III (cytochrome-c reductase) and IV (cytochrome-c oxidase) within the respiration chain of prokaryotic and eukaryotic organisms. Cytochrome-c552 from Thermus thermophilus is a soluble monoheme cytochrome with an unusual high molecular mass (14.2 kDa) and its
primary structure is only distantly related to other monoheme cytochrome amino acid sequences. Remarkable for this cytochrome is its high thermostability. The molecular structure of cytochrome-c_{552} from *Thermus thermophilus* is shown in Figure 47. The polypeptide chain is folded around the heme group. The N-terminal two-thirds of cytochrome-c_{552} cover spatial regions around the heme group that are similar to those observed for other cytochromes. The N- and C-termini and also the C-terminal clamp (thermohelices) with a stabilizing function are labeled in Figure 47. The core of the protein is highly hydrophobic and there is no internal water molecule present which is typical for other cytochromes. The presence of the “thermohelices” with their high concentration of ion pairs and hydrophobic contacts to the residual part of the molecule and the complete absence of internal water molecules could be responsible for the high thermal stability.

### 6.3 Large Molecular Assembly

#### 6.3.1 Crystal Structure of 20S Proteasome from Yeast

The controlled degradation of proteins in the interior of cells is of central significance for many processes that range from cell cycle control and differentiation to cellular immune response. The target protein is labeled for destruction by the covalent linkage of a small protein called ubiquitin and is degraded after adenosine triphosphate (ATP)-driven unfolding in the closed internal chamber of a large protein complex which is known as 26S proteasome (molecular mass 2,000,000 Da). The core and the proteolytic chamber of the 26S proteasome are formed by the catalytic 20S particle (molecular mass 700,000 Da). This particle is flanked at each end by a so-called 19S cap which seems to be responsible for the recognition and unfolding of the ubiquitin-labeled target proteins. The eukaryotic catalytic 20S machinery consists of 14 different but related protein subunits that assemble to the overall structure of 28 protein chains, a monster of the molecular world. The structure of the 20S proteasome from *Saccharomyces cerevisiae* has been elucidated at atomic resolution.\(^{112}\) This is one of the most complex structures that has been determined up to now, excluding symmetrical systems such as viral capsids. It shows that complexity itself is no limit to understanding structure on the atomic level.

The structure analysis is briefly outlined. Crystals could be obtained by the hanging drop vapor diffusion method with a final precipitant concentration of 12% MPD in the drop (pH 6.5). The crystals are monoclinic, space group *P*2\(_1\), cell parameters *a* = 135.7 Å, *b* = 301.8 Å, *c* = 144.7 Å and *β* = 112.6°, and have one 20S particle per asymmetric unit. Data sets with two different inhibitors were collected at the wiggler beamline BW6 at DESY with radiation of \(\lambda = 1.1\) Å and at 90 K temperature. The mean attainable resolution was 2.4 Å. A self-rotation function calculated at 5 Å resolution revealed the orientation of the local twofold axis. The atomic model of the 20S proteasome from *Thermoplasma acidophilum*\(^{71}\) could be used for molecular replacement calculations [program AMORE\(^{51}\)] at 3.5 Å resolution and a prominent solution could be found. The resultant electron density map was cyclically averaged about the local twofold axis. The individual subunits were identified according to their characteristic amino acid

![Figure 47](image-url)
sequences and were built into the map. The final model with the lactacystin inhibitor was refined at a resolution of 2.4 Å to an R-factor of 0.26 consisting of 48,888 protein, 30 inhibitor, 18 magnesium atoms and 1,800 solvent molecules.

The structure of the eukaryotic proteasome is important because it is much more complex than its archaeabacterial relative which has two types of subunits, α and β, only. The α-subunits do not seem to be catalytic but they may self-assemble to form sevenfold rings. In contrast, the β-subunits show catalytic activity but are not able to assemble themselves. The two components assemble themselves to a stack of four rings, two outer α-rings which enclose an inner pair of β-rings. The eukaryotic proteasome retains the important property, however, that the single subunits of the sevenfold rings are different, probably reflecting the increased biological functions. The exact sevenfold symmetry of the particle is lost and a twofold symmetry remains solely to give seven different α- and seven different β-subunits (Figure 48a and b). In the proteasome, the unfolded protein is cut into peptide products in the inner chamber of the 20S particle and these have a length distribution with a center around octa- or nonapeptides. These sizes are appropriate to bind to MHC-class-I molecules.

The term *pesticide* is used to indicate any substance, preparation or organism used for destroying pests. This broad definition covers substances used for many purposes. They are as follows: insecticides, herbicides, fungicides, nematicides, acaricides, lumbricides, growth regulators, insect repellants. The latter two groups are usually included as pesticides, even though they do not kill the target organisms. An enormous spectrum of chemical types of pesticides covers the definition of pesticides. According to their chemical nature, a first rough classification distinguishes between organic and inorganic pesticides. Actually, organic chemical pesticides receive virtually all of the regulatory attention and public concern and these will be the subject of this series of articles. The most important classes of pesticides are the following: organochlorines, organophosphorus, carbamates, triazines, phenoxyacids, phenyl and sulfonyl ureas, acetanilides, benzimidazoles, pyrethroids, diphenylethers, and the recently introduced imidazolinones (see *Herbicides (New Generation): Imidazolinones, Arlyoxyphenoxypropionic Acids/esters, and Diphenylethers, Analysis of*).

The meaning of the term *trace* has changed through time. During the past 35 years, the meaning of trace analysis of pesticides in real-life samples has changed from parts per million (ppm: 1 part in $10^6$), to parts per billion (ppb: 1 part in $10^9$), and currently to parts per trillion (ppt: 1 part in $10^{12}$). Presently, some methods can also detect pesticides at parts per quadrillion levels. In this case, the term *ultrace* is sometimes used.

Before the introduction of organochlorine and organophosphate insecticides in the mid-1940s, the history of pesticide trace analysis coincides with the history of the determination of arsenic-based pesticide residues in foodstuffs. Following a number of deaths occurring between 1855 and 1900, the English Royal Commission, chaired by Lord Kelvin, set a residue limit for arsenic of 1.43 ppm. Even after setting this standard, the controversy about arsenic and some other inorganics (lead, mercury, copper and thallium) used as insecticides and fungicides continued and ceased only after World War II, when less toxic synthetic organic insecticides replaced inorganic ones. At that time, apart from some biochemical assays involving inhibition of the cholinesterase enzyme for monitoring organophosphate insecticides, spectroscopic methods of analysis in connection with color-producing reactions were the only methods used that had the sensitivity needed for analysis of a pesticide at the ppm level. Following the introduction of dichlorodiphenyl-trichloroethane (DDT), the first practical method for determining DDT residues in foods was proposed in 1945 and persisted until it was later replaced by gas chromatographic methods. While laboratory scientists were slowly developing new spectrophotometry-based methods for determining ppm residues in food of new insecticides of the same class of DDT, that is organochlorine insecticides (see *Organochlorine, Pyrethrin and Pyrethroid Insecticides: Single Class, Multi-residue Analysis of*), and some recently introduced organophosphate (see *Organophosphorus Pesticides in Water and Food, Analysis of*) insecticides, the latter scenario was changing both rapidly and greatly. Starting from the early 1950s, the number of organic pesticides adopted for crop protection dramatically increased. Several other synthetic compounds increased the classes of organochlorines and organophosphates which, together with the new class of carbamates (see *Carbamate and Carbamoyloxime Insecticides: Single-class, Multi-residue Analysis of*), came into wide use against insects. Phenoxyacids (see *Phenoxy Acid and Other Acidic Pesticides: Single Class, Multi-residue Analysis of*), triazines (see *s-Triazine Herbicides and their Transformation Products, Multi-residue Analysis of*) and phenylureas (see *Phenyl- and Sulfonylurea Herbicides: Single Class, Multi-residue Analysis of*) replaced chlororanes and borates for inhibiting the growth of weeds. Dithiocarbamates replaced copper salts and sulfur as fungicides. In addition, a number of organics were increasingly used as nematicides, rodenticides and fumigants. As compared to inorganic pesticides, the relatively low acute toxicity of these new pesticides encouraged their widespread use and abuse for agricultural and nonagricultural purposes. As a consequence of their widespread use, any kind of environmental compartment was increasingly contaminated by pesticides.

In the early 1960s, the vulnerability of surface water to pesticides was recognized and bioaccumulation in fish, zooplankton and aquatic plants investigated. In the same years, evidence was obtained for leaching of pesticides through the soil and contamination of groundwaters. At the same time, the science of modern toxicology brought to light that chronic exposure to pesticides was the most serious problem. Several long-term pathologies, including cancer, mutagenesis and teratogenesis, could be provoked by daily intake of very small amounts of pesticides and related compounds. It appeared, then, that colorimetric methods were inadequate for monitoring a very large number of small amounts of pesticides having a broad range of polarity and different functional groups in a wide variety of complex sample matrices.

In the early 1970s, the development of gas chromatography (GC) with capillary columns coupled to sensitive and
selective detectors (see Gas Chromatography and Super-critical Fluid Chromatography with Selective Detection in Pesticide Analysis) revolutionized pesticide trace analysis. Application of this technique allowed separation at nanogram levels of many pesticides from each other and often from potential interfering compounds into a single run. This initiated the development of the multi-residue analysis of pesticides (see Multiclass, Multi-residue Analysis of Pesticides, Strategies for).

Since the first research papers reported in the mid-1960s describing coupling of a mass spectrometer with a gas chromatograph (see Gas Chromatography/Mass Spectrometry Methods in Pesticide Analysis) and later with a liquid chromatograph (see High-performance Liquid Chromatography/Mass Spectrometry Methods in Pesticide Analysis), it appeared that this highly specific technique could become the ultimate tool to solve problems of false positives which may frequently occur in the analysis of pesticide traces in complex matrices. Data obtained by using a mass spectrometer as a detector are so reliable that today no analytical result is definitively accepted if it is not supported by mass spectra. The evolution of liquid chromatography into the analytical technique known as high-performance liquid chromatography (see High-performance Liquid Chromatography Methods in Pesticide Residue Analysis), occurring in the late 1970s, afforded the tool for analyzing those pesticides and pesticide degradation products that, being nonvolatile, highly polar, and thermally labile, were not amenable to direct gas chromatographic analysis.

In the last decade, the use of enzyme-linked immunoadsorbent assays for specifically and rapidly determining traces of a single pesticide or a single class of pesticides has been rapidly growing (see Immunochemical Assays in Pesticide Analysis). Immunoassays require decreased sample preparation and offer high sample throughput, so they can greatly help analysts when chromatographic methods are difficult and time-consuming.

Recently, capillary electrophoresis has emerged as a valid alternative technique to liquid chromatography for analyzing ionic and ionizable pesticides, such as phenoxyacids, some cationic herbicides (see Pesticides (New Generation) and Related Compounds, Analysis of) and sulfonylureas (see Phenyl- and Sulfonylurea Herbicides: Single Class, Multi-residue Analysis of). Analytical methods for determining pesticides have different purposes. The particular objective to be achieved can influence the choice of the analytical methodology.

- Compliance with standards. Any material destined for human consumption has to be tested to enforce national residue limits. Analytical methods for determining as many pesticides as possible are needed, even though single pesticide methods may also be required to attain the desired scope. The method sensitivity is not always the parameter of choice, as different countries can have very different maximum acceptable concentration levels.
- Emergency response. In this case, the speed of analysis is the principal requirement. Pollution incidents can pose a sudden need for analytical methods for an unpredictable range of pesticides. Method sensitivity and specificity are not key factors in these situations.
- Behavior and fate of pesticides. Methods of analysis are needed for monitoring studies aimed at understanding how pesticides behave in the environment so that predictive models can be developed and tested. The sensitivity and accuracy of such methods should be adequate for likely predicting compliance with national standards.
- Laboratory and field tests on new pesticides. Manufacturers of pesticides need sensitive and specific methods of analysis to study the persistence, the mobility and the degradation pathway of the pesticides in the laboratory and field.

A particular type of analysis is that aimed at determining concentration levels in a certain matrix of chiral pesticides (see Chiral Pesticides and Polychlorinated Biphenyl Congeners in Environmental Samples, Analysis of). Chiral compounds show enantiomeric selectivity in reactions with biological systems. Biological activity in soil or water environments may result in the preferential reactivity of one enantiomer of a pesticide in terms of microbial degradation, biological uptake, metabolism and/or toxicity.

Today, there are more than 1800 basic chemicals that are used as active ingredients of pesticides dispersed in approximately 33 600 formulations. Over the last 20 years, in the United States about $15 \times 10^6$ kg of pesticides were spread in the environment. This situation has urged local governments to introduce more restrictive regulations banning some dangerous pesticides and lowering the maximum admissible concentrations of pesticides in drinking water and foodstuffs. An enacted European Community Directive states that a single pesticide cannot be present in water destined for human consumption in concentrations higher than $0.1 \mu L^{-1}$.

The complex matter of pesticide trace analysis in environmental samples can be afforded by three basic approaches. The first approach is that of developing/using multi-residue methods (MRMs) able to determine as many as possible pesticides and pesticide metabolites having a broad range of polarity and structural properties in a wide array of sample matrices at the required sensitivity limit. These methods are employed usually by analysts in regulatory and compliance laboratories and by those conducting monitoring and surveillance...
programs. Still today, GC remains the most popular technique for accomplishing MRMs, as demonstrated by the fact that the five principal MRMs invariably involve this technique as an effective identification/confirmation tool. After some pioneering works in 1963, several other MRMs followed as analysts have attempted to deal with the increasing number of pesticides. However, many pesticides and pesticide metabolites cannot be determined by these MRMs, because they are not amenable to direct GC analysis. In 1988, the Congress’s Office of Technology Assessment of the USA reported that official MRMs can determine only 200 of the approximately 750 pesticides and related compounds that must be tested. This gap has stimulated researchers to develop MRMs based upon liquid chromatography with ultraviolet and mass spectrometric detection for determining those pesticide classes, such as phenylureas and carbamates, and pesticide metabolites which cannot be easily determined by GC. Very recently, a Canadian group of researchers has elaborated a method for determining 199 pesticides in vegetable matrices which involves both high-resolution GC/mass spectrometry and liquid chromatography with fluorimetric detection.

A second approach is that of developing/using selective MRMs for monitoring compounds of the same class or having similar structural properties. The US Environmental Protection Agency (USEPA) has recently developed a method (Method 531.1) for selectively determining carbamate insecticide residues in drinking water involving liquid chromatography and fluorescence detection with a post-column derivatization reactor.

The third approach is that of developing/using single residue methods (SRMs) that are effective for the analysis of one particular pesticide and its degradation products in a particular substrate. This approach is generally used by pesticide manufacturers who are responsible for supplying data from field and metabolism studies in support of registration of pesticides. SRMs are also followed by geochemists who are interested to know the fate of a pesticide in the environment and by analysts when a compound of particular interest cannot be included for a number of reasons in any of the usually adopted MRMs. Recently, the USEPA has developed a suitably tailored method based on high-resolution GC with selective detection for determining ethylenethiourea, which is a toxic degradation product of dithiocarbamate fungicides, in water.

These methods usually share at least one of the analytical preparative steps before final analyte identification and quantification. They may consist of isolating the analytes from the matrix and enriching them by solvent or solid-phase extraction, supercritical fluid extraction, or cleanup by liquid–liquid partitioning, adsorption onto suitable adsorbents and/or gel permeation chromatography, bioaffinity chromatography, sweep codistillation.

The aim of this series of articles is that of giving an up-to-date overview of the analytical methodologies and instruments used and emerging strategies for monitoring pesticide traces in environmental samples, such as water (see Pesticides in Water: Sampling, Sample Preparation, Preservation), vegetables, soil and sediments (see Soil and Sediments: Pesticides Content Sampling, Sample Preparation, and Preservation) and biota (see Biological Matrices: Pesticides Content Sampling, Sample Preparation and Preservation and Herbicide Residues in Biota, Analysis of).

Environmental pollution is a world-wide problem. Consequently, the demand for pesticide analysis in biological samples is increasing. In most cases, the availability of the test result depends on the suitability of sampling, sample preservation, and sample preparation which must satisfy the need. However, there is no reference method. This paper summarizes sampling and sample preparation and preservation methods for the case when the compound to be detected is not known.
tests and/or acetyl-cholinesterase (Ac-ChE, EC: 3.1.1.7) activity in erythrocytes must be conducted at the same time. In addition, when treating pesticide-intoxicated patients with low Ps-ChE activity in serum, it is necessary to identify the causal substance – OP or CPs. This is because in the case of OP intoxication, the administration of paralidoxime-indole (PAM) is effective in enabling the early recovery of Ps-ChE activity. However, in the case of CP intoxication, PAM administration tends to delay and restrict the natural recovery of Ps-ChE activity, so its use is prohibited.

GC and HPLC, which feature easy operability, high measurement sensitivity, and specificity, are useful analytical methods employed in many laboratories in recent years. In both methods, however, peak identification is based on only the elution from the used column. Accordingly, when complex matrices such as biomedical samples are measured, a complex clean-up operation for samples is necessary in some cases.

However, although MS, particularly GC/MS, is regarded as an analytical method with extremely high sensitivity and specificity, it has the disadvantage of requiring an expensive instrument and a specialized operator.

### 1.3 Selection of Targets for Measurement

“Pesticide” is a generic term for several hundred kinds of chemical substances. In life-saving treatment, however, there is no great difference among intoxication cases caused by different pesticides (Table 1). The only matter worthy of note is deciding whether PAM should be administered to victims of poisoning. As previously mentioned, the administration of PAM, which is an antagonist to relatively high-toxicity OP, promotes the recovery of the Ac-ChE activity in OP intoxication cases, but delays the natural recovery of Ac-ChE activity in cases of CP intoxication. Therefore, in clinical medicine, particularly emergency medicine, two groups – OP and CPs – are the most important targets for measurement.

In the fields of legal and preventive medicine, a wide range of compounds, including organochlorinates, herbicides, and dioxin-like compounds, should be selected as measurement targets.

### 2 SAMPLING

#### 2.1 Which Sample Should be Measured?

When pesticide intoxication is suspected, blood, urine, digestive tract contents or abluents, and tissues are mainly selected as the measurement sample. Among these, blood is the most important sample, as the detection of a residual pesticide in a biomedical sample in clinical medicine is conducted to save life. The subsequent course of pesticide-intoxicated patients normally depends on the type of pesticide (toxicity) and its concentration in the blood, so the blood concentration should be measured first. It is recommended that not less than 50 ml (if possible) of the circulating blood be sampled prior to the administration of other therapeutic drugs.

At the time of intoxication caused by trans-respiratory tract ingestion, however, the causal substance in the blood can rarely be identified. In addition, at oral ingestion, before the causal substance enters the bloodstream from the digestive tract, it is obviously pointless to sample the blood for measurement target. In such a case, it is effective to use the digestive tract contents or abluents as samples. Fortunately, these samples generally contain unchanged pesticides that have not yet been metabolized at high concentration, so pesticides can easily be detected. However, it is impossible to determine the prognosis of the patient, even though the causal substance can be identified and the ingested amount can be estimated.

If pesticide intoxication is suspected but cannot be proven based on testing of the blood, it is often effective to use urine as a measurement sample. In particular, most OP and CPs are easily metabolized in living bodies, as they decompose in urine and are excreted relatively early. The concentration of pesticides in the blood shows an elimination pattern similar to that of pharmaceuticals. That is, the pesticide concentration immediately after ingestion quickly decreases as the pesticides spread to the tissues (α curve), then, gradually drops due to metabolism and excretion (β curve). Regrettably, the half-life of individual pesticides in human blood is unclear, so we must refer to data obtained from experimental animals. In our experience, a major portion is excreted within 2–5 days.

Low-polarity pesticides (halogen-element OP, organochlorinates, thiophosphate esters, etc.) move from the bloodstream to tissues quickly, and tend to remain in organs. In such a case, it is useful to use fat tissues and organs as measurement samples, but it is often difficult to collect them from a living body.
2.2 What Should be Measured?

Pesticides taken into living bodies are metabolized through various routes, either enzymatically or non-enzymatically. Metabolites are excreted into urine at a high concentration for an extended period. It is therefore important to understand the metabolism of pesticides, and to detect not only pesticides but also metabolites at the same time. Pesticide metabolism in living bodies is briefly described below.

\[
\text{Phosphatase}\quad \text{H}_3\text{PO}_4 \quad \text{R}_1\text{O}_P \text{O} \quad \text{R}_2\text{O} \quad \text{R}_3 \quad \rightarrow \quad \text{R}_1\text{O}_P \text{O} \quad \text{R}_2\text{O} \quad \text{R}_3\text{OH} + \text{R}_3\text{OH}
\]

Scheme 1  Phosphate ester hydrolysis in phosphates.

2.2.1 Organophosphorus

OP are easily metabolized in living bodies. The primary metabolic route can be classified as (1) hydrolysis, (2) oxidation, and (3) transmethylation.

The hydrolysis of phosphate ester by phosphatase occurs specifically at a site of the elimination group in three ester bonds of OP (Scheme 1). Phosphatase, however, does not act on compounds (phosphorothionates and phosphorodithionates) that have the \( \text{P=S} \) bond. In malathion and dimethoate, side-chain ester hydrolysis takes place (Scheme 2).

Drug-metabolizing enzymes present in hepatic microsome cause various oxidation reactions, such as oxidation of the \( \text{P=S} \) bond to the \( \text{P=O} \) bond, oxidation of the thioether bond, the hydrolysis-like reaction of the \( \text{P=S} \) compound, and the O-deethylation or O-demethylation reaction (Scheme 3). Methyl-transferase causes O-demethylation, and then tranmethylation to glutathione.

2.2.2 Carbamates

Here, we will explain metabolism in living bodies, using carbaryl (NAC), a typical CP, as an example.

NAC does not accumulate in living bodies, but is excreted through two metabolic routes. In the first route, NAC is hydrolyzed into 1-naphthol and \( N \)-methylcarbamic acid. The former, 1-naphthol, further becomes glucuronic acid or sulfuric acid conjugates to be excreted outside the body. The latter, \( N \)-methylcarbamic acid, is decomposed into carbonic acid and methylamine.

In the second route, NAC metabolites are produced by methylation of the \( N \)-methyl group and hydroxylation of the naphthyl group (4-OH, 5-OH, and 5,6-dihydroxyl). These metabolites then turn to glucuronic acid or sulfuric acid conjugates to be excreted outside the body.

2.2.3 Organochlorinates

Generally, organochlorinates undergo virtually no enzymatic or non-enzymatic metabolism, and easily

\[

\]

Scheme 3  Metabolism by drug-metabolizing enzyme in phosphorothionates, phosphorotheioates and phosphorodithioates.
accumulate in living bodies. This, however, does not mean that they are never metabolized (Schemes 4–10).

Organochlorinates accumulated in fat circulate through fat tissues, the blood stream, and the liver. They are metabolized in the liver by various enzymes at a considerably slower rate than that of fat metabolism. That is, organochlorinates are converted to highly polar substances through various oxidation reactions, such as aromatic-ring and side-chain hydroxylation, O- or N-dealkylation, S- or N-oxidation, and epoxidation, and combinations of dehydrogenation, dehydrochlorination, reduction, hydrolysis, and exchange reaction. These substances are excreted as they are or as conjugated substances (glucuronic acid, sulfuric acid, amino acid). In such a case, unchanged organochlorinates and their metabolites are excreted not only into urine but also into bile in large quantities, and via the duodenum in the form of human waste.

3 SAMPLE PREPARATION

3.1 Organophosphates

Table 2 summarizes recent reports on sample preparation in the analysis of OP in biomedical samples.

Since OP are low-polarity compounds, organic solvents with a polarity lower than that of the sample matrix should be used for extraction, purification, and concentration.

3.1.1 Liquid–Liquid Extraction

In sample preparation for the analysis of OP in tissues or body fluids, extraction is firstly performed using MeCN.

Generally, OP in the extract are transferred to the n-hexane layer by distribution with NaCl and n-hexane, and become suitable for use as a measurement sample through the processes of drying using sodium sulfate anhydride and concentration at 50°C or below. If the matrix contains...
a large quantity of fats, fats in the concentrated \( n \)-hexane layer must be removed. In the analysis of OP in the bovine liver, D.M. Holstage et al. removed fat components by a clean-up method combining GPC using an S-X3 biobeads column with solid-phase extraction (SPE) using a silica gel cartridge,\(^9\) Organic solvents other than \( n \)-hexane used for distribution include chloroform, dichloromethane, and \( n \)-hexane/acetone liquid mixture.

Incidence of intoxication caused by glyphosate, a highly water-soluble OP, has increased in recent years. M. Tomita et al. analyzed glyphosate in human serum by deproteinization using perchloric acid (PCA) washing the supernatant with ethyl ether, and performing CE,\(^{21}\) or

by cleaning the deproteinized supernatant with PCA by anion exchange and using HPLC.\(^{23}\)

### 3.1.2 Solid-phase Extraction

SPE is a technique frequently used to analyze pesticides in environmental water, but only a few cases have been reported in which only SPE has been used for analysis in biomedical samples. Kawasaki et al. used HPLC/MS to analyze 21 types of OP in human serum and urine. Using adsorption to a diatomaceous earth cartridge, elution with an \( n \)-hexane/diethyl ether mixture,\(^{27}\) and an octadecasil (ODS) column, they employed the one-step sample clean-up method using elution with MeCN.\(^{29}\)

### 3.2 Carbamates

#### 3.2.1 Liquid–Liquid Extraction

Most CPs are insoluble or hardly soluble in water. CPs are highly soluble in organic solvents such as MeOH, EtOH, acetone, chloroform, and dichloromethane, but hardly soluble in petroleum-based hydrocarbons and xylene. Accordingly, organic solvents to be used for extracting CPs from samples must be selected with consideration of the solubility of the CPs to be detected, and the types of coexistent substances in sample matrices. For analysis of CPs in biomedical samples, an extraction method using acetone is employed in many cases. For analysis of matrices containing a large quantity of fat, dichloromethane is used for extraction. In such a case, fat removal may be necessary, depending on the CP detection methods. After the extract is dried under reduced pressure, CPs are recovered into the MeCN layer by distribution using \( n \)-hexane and MeCN, and the MeCN layer dried again under reduced pressure for use as measurement samples.

3.2.2 Solid-phase Extraction

Table 3 summarizes recent reports on sample preparation in the analysis of CPs in biomedical samples.

Using an ODS cartridge, Bakowski et al. eluted 10 types of CPs in liver with 70% MeOH (in water), and analyzed them by GC/MS.(16) Kawasaki et al. eluted eight types of CPs in serum with dichloromethane, using a diatomaceous earth cartridge, and analyzed them by HPLC/MS.(28) Holstage et al. (9) and Kawasaki et al. (29) have reported on the simultaneous extraction and analysis of OP and CPs.
### 3.3 Organochlorinates

Organochlorinates are used extensively as insecticides, sterilizers, and herbicides. In particular, those used as insecticides are extremely toxic to living bodies, so the highest priority should be given to the clinical analysis of these organochlorine insecticides. The use of most organochlorinates in insecticides is currently prohibited or limited. However, they remain in animal foods such as meat and fish, and accumulate in living bodies when such foods are consumed.

Low-polarity organic solvents such as *n*-hexane and chloroform are used to extract organochlorinates from biomedical samples. In such a case, pigments and fats in samples are extracted simultaneously, so a clean-up method using a florisil column may also be employed (Table 4).

Though PCB are not pesticides, they are extracted by the above method. They can be measured at the same time as organochlorinates, by gas chromatography/electron capture detection (GC/ECD) or GC/MS.

### 3.4 Herbicides

Alkylidipyrimidium salts, organochlorinates, triazines, phenolate, phenoxyate, and anilinate compounds are used as herbicides. Among them, compounds other than alkylidipyrimidium salts and triazines have a relatively weak toxicity to the human body.

Alkylidipyrimidium salts (paraquat, diquat, morfamquat), particularly, are highly toxic compounds. In particular, the number of acute intoxication patients caused by paraquat and/or diquat has not decreased. In these intoxications, the blood concentration must be quickly lowered in order to save the patient’s life. Accordingly, it is clinically important to measure the concentration of the two kinds of pesticides in the blood. HPLC is frequently used to measure paraquat and diquat in the blood or urine. Supernatant obtained following deproteinization with PCA (approximately 5%) can be used for test samples. In some cases, such protein-free supernatant is cleaned by ion exchange or through the use of a reversed-phase column ODS.

FID, flame ionization detection; GC/FID, gas chromatography/flame ionization detection; EDTA, ethylenediaminetetraacetic acid; PAC, chloridazon, 5-amino-4-chloro-2 phenylpyridazin-3(2H)-one; TCA, trichloroacetic acid.
Triazines also show comparatively high toxicity for mammals. Dichlormethane is commonly used as the extraction agent from the biomedical samples. However, solvent partitioning and/or additional clean-up with a C8 or C18 column are sometimes needed.\(^{(25,31)}\)

Table 5 summarizes recent reports of herbicides analysis in biomedical samples.

### 3.5 Other Pesticides

Ivermectin, which has a broad spectrum, has been used as an antibiotic in recent years, and its effect on the human body has been extensively investigated.

LLE and SPE extraction methods are utilized to determine ivermectin concentration in human, bovine, and sheep serum\(^{(4,23,26)}\) (Table 6).

#### 4 SAMPLE PRESERVATION

Pesticides in biomedical samples should be measured as quickly as possible after sampling. Since most pesticides are unstable in highly polar solvents and acidic or alkaline solutions, their decomposition during sample preservation may result in erroneous measurements and incorrect interpretations. However, if samples must be preserved, they should be preserved in completely sealed glass containers at as low a temperature as possible. Antiseptics may interfere with measurement, so their use should be avoided.

If the compounds to be detected are known, make sure you fully understand their characteristics and select the optimum preservation method for them.

### 4.1 Blood (Plasma and Serum)

Blood is the biomedical sample most frequently used, and its value for clinical utilization is very high. As previously mentioned, many types of pesticide decompose naturally in solution, so the blood must be very carefully preserved.

Figure 1 illustrates a typical example of natural decomposition of pesticides during sample preservation. NAC was added to drug-free serum to produce a final concentration of 10 µg mL\(^{-1}\) and the sample was preserved at 4°C and −20°C. 400 µL of acetonitrile was added to 200 µL of serum for deproteinization, and NAC and 1-naphthol concentrations of supernatant was measured by HPLC/UV (220 nm).

Even with preservation at −20°C, NAC was decomposed.

### 4.2 Urine

Principally, the preservation of urine samples for pesticide analysis should be the same as that of blood. After sampling the entire amount of urine confirm that its pH is neutral and store it at a temperature of −20°C or below. As antiseptics may make measurement difficult, their use should be avoided.

### 4.3 Other Biomedical Fluids

The contents or abluents of the digestive tract can be used as biomedical samples for pesticide analysis, in addition to blood and urine. Whole capsules or tablets are occasionally found in the digestive tract contents. Such residues should be measured individually. Accordingly, after centrifuging the sample, the residue and supernatant should be preserved in separate containers.

### 4.4 Tissues

The liver is the main detoxifying organ in living bodies, and many drug toxins accumulate there. For this reason,
the liver can be the optimum organ for sampling. Since it is difficult to obtain a liver sample from a living body, the liver is often used for pesticide analysis in dead bodies. After examining marked lesions such as necrosis and color change in the liver, collect at least 100 g and freeze-preserve it at $-20^\circ C$ or below.

### 5 CONCLUSION

"Pesticide" is a generic term for several hundred types of compounds. In pesticide analysis, there is currently no reference or recommended method for sampling, sample preservation, or pesticide detection. If it is clear which pesticides are to be detected, methods appropriate for individual compounds should be selected. In the analysis of pesticides in biomedical samples, however, it is often unclear which compounds are to be detected. Accordingly, primarily for such cases, this article describes sampling, preparation of test solution, and preservation of samples.

If humankind is to coexist successfully with pesticides, demand for pesticide analysis in biomedical samples is expected to increase in the future. Standardization in this field and the establishment of information networks are urgently needed.

Carbamate and Carbamoyloxime Insecticides: Single-class, Multiresidue Analysis of

Maarten Honing
NV Organon, Oss, The Netherlands

1 Introduction

Large quantities of modern pesticides such as the N-methyl- and carbamoyloxime carbamates (over 1000 t of the N-methylcarbamate carbaryl) are used for agricultural as well as for nonagricultural purposes. The European Union (EU)-permitted concentration levels of these insecticides and their related transformation products in drinking water is 0.1 µg L\(^{-1}\), and the maximum for the total pesticide content has been set to 0.5 µg L\(^{-1}\). Many analytical procedures, focusing on sample pretreatment, column chromatographic separation, and sensitive detection, have been reported for the trace-level determination of these compounds. This article surveys the application of these procedures, focusing on sample pretreatment, column chromatography, and sensitive detection, have been reported for the trace-level determination of these compounds. This article surveys the application of these subclasses. The degradation products are generally oxidized derivatives (such as aldicarb sulfone from aldicarb), or alcohols formed by saponification of the carbamic acid group (such as aldicarb sulfone from aldicarb). The general degradation pathways of carbamate pesticides have been discussed by Schlagbauer et al. Figure 1 shows a general representation of these subclasses. The degradation products are generally oxidized derivatives (such as aldicarb sulfone from aldicarb), or alcohols formed by saponification of the carbamic acid group (such as 1α-naphthol from carbufen). The general degradation pathways of carbamate pesticides have been discussed by Schlagbauer et al. and several reports dealt with the fate of specific carbamates: aryl-N-methylcarbamates, benomyl, and oxime-N-methylcarbamates. The (bio)degradation of some carbamates in various matrices is explain in this article. Chromatographic resolution is most effective, when gas chromatography (GC) is used. Unfortunately, thermal degradation of some carbamates in the injector takes place, making liquid chromatography (LC) the separation technique of choice despite the fact that some carbamates cannot now be separated. Capillary electrophoresis (CE) offers better separation efficiency but is still not a robust technique. Another way to solve the coelution problem is the application of mass spectrometry (MS). Utilizing the selected ion monitoring mode, coeluting compounds can be quantified. MS adds an extra separation step because ionized compounds are separated by the mass-to-charge ratio. Application of the ionspray (ISP) and the heated nebulizer (HN) interfacing techniques makes possible the quantification of carbamates at trace levels as low as 0.1 ng L\(^{-1}\) in drinking water, without any sample preconcentration. Furthermore, MS also offers the ability to confirm the identity of the compounds. On-line SPE in combination with liquid chromatography/mass spectrometry (LC/MS) or, better, liquid chromatography/tandem mass spectrometry (LC/MS/MS) is the best method for the quantification and structural confirmation of carbamate pesticides at concentration levels of 0.1 ng L\(^{-1}\) or lower.

1 INTRODUCTION

The use of nonpersistent carbamate and carbamoyloxime pesticides (which have replaced organochlorine and organophosphorus compounds) is common practice, mainly because of their broad spectrum of activity, high pesticide effectiveness, and generally low mammalian toxicity. A large variety of carbamates is currently in use. Their application as an insecticide, fungicide, or herbicide is related to the molecular structure. The insecticides have the N-substituted carbamate moiety and, generally, an aromatic ester or an oxime function. The fungicides have either a benzimidazolyl ester, a pyrimidyl ester or a (bis)dithiocarbamate group. The herbicides are N-alkyl or N-aryldithiocarbamates. Figure 1 shows a general representation of these subclasses. The degradation products are generally oxidized derivatives (such as aldicarb sulfone from aldicarb), or alcohols formed by saponification of the carbamic acid group (such as 1α-naphthol from carbufen). The general degradation pathways of carbamate pesticides have been discussed by Schlagbauer et al. and several reports dealt with the fate of specific carbamates: aryl-N-methylcarbamates, benomyl, and oxime-N-methylcarbamates. The (bio)degradation of some carbamates in various matrices...
has also been studied.\(^{11,12}\) The effects of photolysis have also been investigated.\(^{13}\)

Many chromatographic separation techniques have been developed for the determination of carbamate pesticides and in some cases their degradation products. Other methods in use are bioassays,\(^ {14,15}\) thin-layer chromatography,\(^ {16}\) and calorimetry.\(^ {17}\) More recently, biosensor-based\(^ {18,19}\) techniques have been developed and applied to the determination of various types of pesticides. In most cases, these techniques are used for the quantitative analyses of a limited amount of compounds, typically one target compound in a foodstuff, for example. CE, a chromatographic technique using a potential difference between the two ends of the capillary, has been applied to the analysis of polar pesticides.\(^ {20,21}\) However, the applicable sample volume is restricted and the robustness of the technique has still to evolve. This article focuses mainly on GC- and LC-based analytical methods for the determination and identification of carbamates and their transformation products, in various environmental matrices.

The large amounts of carbamate pesticides used since the late 1970s requires extensive monitoring in all types of environmental samples. In order to do this, validated analytical procedures need to be developed that are able to determine concentration levels down to 0.1 µg L\(^{-1}\) for drinking water.\(^ {22}\) Ideally, such procedures should be able to assess the carbamates and their transformation products, so as to reduce analysis time and expense.

Although not exhaustive the references given here provide a good representation of the items of interest in carbamate determination. The majority of the target and multiresidue analytical procedures reported are based on GC and LC techniques.\(^ {22-24}\) This article is divided into three sections: (1) sample preparation from water, plant materials, and soil; (2) GC, LC and CE separations; and (3) ultraviolet (UV), fluorescence, electrochemical detection (ECD) and MS detection in LC. The discussions lead to the conclusion that LC/MS with proper clean-up and preconcentration procedures is the method of choice for the multiresidue analysis of carbamate and carbamoyloxime carbamate insecticides.\(^ {25}\)

### 2 SAMPLE PREPARATION

It is of utmost importance to pay care to the sample, because the compounds of interest are susceptible to degradation by hydrolysis at basic or neutral pH,\(^ {23}\) prolonged exposure to light, and metabolism. For example, adjustment of the pH of an aqueous sample, from pH 9.5 to 6.5, keeps the solution stable for 1 week. The best procedure is to acidify and extract the aqueous sample directly after collection. Light-induced degradation may be minimized by storage in the dark, and metabolic degradation may be prevented by performing the extraction directly after sampling. As the increased polarity of the (bio)degradation products will generally add to the complexity of the problem, extraction and clean-up also require careful attention.

Various methods have been applied to the extraction of carbamates and some of their transformation products, from environmental matrices such as surface or groundwater,\(^ {26-30}\) plants,\(^ {39-50}\) and soil.\(^ {50-53}\) The extraction procedures for water samples, biological materials and soil have been reviewed.\(^ {53}\) The Environmental Protection Agency (EPA) procedure for the determination of N-methylcarbamates in drinking water\(^ {38,54,55}\) requires neither extraction nor clean-up (500 µL samples are injected directly into the analytical system). Many extraction procedures are available, such as LLE, solid–liquid extraction (SLE), SPE, or supercritical fluid extraction (SFE).\(^ {56-60}\) With LLE the analytes are partitioned between two immiscible liquid phases, generally water and an organic solvent. In SPE the analytes are first adsorbed from a liquid sample onto a solid sorbent and then selectively desorbed, often after washing of the precolumn. In SLE the compounds are partitioned between the solid sample and a liquid phase, generally an organic solvent and/or water. In SFE the analytes are directly extracted into a supercritical fluid. LLE and SPE are commonly used for water samples, whereas SLE (using for instance Soxhlet extractors or sonication) and SPE are mainly applied to foodstuff, soil, and sediment samples. Clean-up is generally required for foodstuff, sediment, or soil extracts, using liquid–liquid partitioning or adsorption chromatography. Extracts of aqueous samples hardly ever require further clean-up.

The efficiency of sample preparation, both for extraction and clean-up, is usually tested by recovery
experiments, in which samples are spiked with known quantities of the analyte. The recovery itself as well as its reproducibility – as a relative standard deviation (RSD) – are the key quality parameters for sample treatment. If the efficiency is high (over 80%) and reproducible (RSD values of a few percent), a correction for analyte losses can safely be carried out. The selection of a sample preparation method is strongly dependent on the recovery and its reproducibility and on the sample type (aqueous, solid, biological), but aspects such as treatment time and consumption of chemicals should also be considered. In the following discussion, sample preparation for aqueous samples, biological materials, and soil samples (mostly solids) are treated separately.

2.1 Aqueous Samples

A variety of parameters influence the extraction efficiency of LLE and SPE, which are commonly used for the extraction of water samples. Although LLE is still applied, it has been replaced by SPE mainly because it can be coupled on-line to subsequent analytical procedures and smaller quantities of organic solvents are used. Both the procedures and the parameters influencing the extraction efficiency are discussed below.

Various solvents may be used in LLE to obtain a satisfactory partitioning of the analytes between water and an organic phase. Dichloromethane is mainly applied for carbamate extraction, although chloroform, toluene, and benzene are also used. The extraction efficiency is influenced by the acidity and ionic strength of the solution, the nature of the sample (such as the presence of particulate material), the volume ratio of the phases, and the number of subsequent extractions. In a typical extraction procedure, one liter of water is acidified and extracted with three portions of the solvent (totaling 100 mL). The extract is subsequently evaporated to dryness and, prior to analysis, redissolved in a small volume of a suitable solvent, there by gaining sensitivity.

The sorbents used for extraction and clean-up with SPE include Amberlite™, Carbotrap B™, and bonded silica phases, many of which are commercially available, often prepacked in disposable cartridges. The choice of an appropriate sorbent, washing and elution solvent is of crucial importance for the extraction and, hence, several studies on suitable phases for carbamate extraction have appeared.

The differences in the sorption behavior of carboxamides on a polar, alkyl-bonded silica phases may give rise to a wide range of breakthrough volumes. Low breakthrough volumes often cause a low recovery for the more polar carboxamides, such as aldicarb, methomyl, and oxamyl (see Table 1). As a consequence, the simultaneous determination of the oxime and aryl N-methylcarbamates is rather difficult when using a polar phases. Although SPE with a polar phases generally provides a better reproducibility than LLE, the recoveries for the polar carboxamides are lower than with LLE.

A comparative study on LiChrosorb RP-18 and Carbotrap B™, using a variety of N-methylcarbamates (and 2 L samples), showed that Carbotrap B™ gives a recovery of about 90% for some of the oxime and aryl N-methylcarbamates (oxamyl 89%, methomyl 93%, carbofuran 98%, and carbaryl 96%; RSDs not reported). The extraction time could be seriously reduced by applying a flow rate of 150–160 mL min⁻¹ (65 × 14 mm inner diameter (i.d.) column). However, the use of Carbotrap B™ resulted in contaminated blanks, and extensive conditioning of the sorbent was therefore necessary. Besides, Carbotrap B™ does not lend itself for the analysis of large numbers of samples.

In another study, cartridges containing a low-carbon LiChrosorb RP-18 sorbent (C₁₈/OH) were tested, using a variety of carboxamides (and 50 mL samples). All compounds tested gave recoveries of 80–100% (RSDs 1–7% at the 0.1 µg L⁻¹ level), except for butocarboxim sulfoxide (76%), ethiofencarb sulfoxide (55%) and thiofanox sulfoxide (42%). The low recovery of the latter three compounds remains unexplained and contrasts with

the satisfactory recovery when using LiChrosorbm RP-8 and RP-18.\(^{(27)}\) The C_{18}/OH phase has a retention capacity comparable to that of Carbopack B\(^m\) but, fortunately, contamination is much less of a problem. By way of illustration, the recoveries for six selected carbamates with three commercially available phases are listed in Table 2.

In subsequent studies, various parameters which influence the preconcentration step, such as the rate of sample loading, the particle size of the sorbent, and the amount of sorbent needed, were investigated. No significant influence of the sampling rate was found; small particles (10 \(\mu\)m) and minimal amounts of sorbent are to be preferred.\(^{(30,31)}\)

On-line coupling of SPE with LC, employing precolumns with bonded-silica phases or so-called membrane extraction disks and desorption by the LC eluent, has been reported.\(^{(33)}\) If a sufficiently sensitive mode of detection is used, sample volumes can be reduced dramatically,\(^{(27)}\) and breakthrough is largely prevented – on-line extraction of 10 mL samples using these disks, and LC combined with on-line hydrolysis, derivatization, and fluorescence detection,\(^{(27)}\) gave good results (recoveries of 80–100\%, RSDs of 3–6\%) for the oxime N-methylcarbamates.\(^{(32,33)}\)

The selection of either LLE or SPE should primarily be based on performance, i.e. on recovery and reproducibility. Although most official methods are based on LLE procedures, such as from the National Pesticide Survey,\(^{(54,55)}\) these procedures generally have several drawbacks related to more practical aspects.

The treatment of (typically) 1 L of sample precludes on-line coupling of LLE to LC and makes the procedure laborious and time-consuming. Furthermore, the formation of emulsions and the necessary solvent evaporation may cause practical problems with regard to evaporation and concentration. Moreover, the considerable volumes of inflammable and sometimes toxic solvents required for LLE cause waste problems. The main advantage of SPE over LLE is the possibility of on-line coupling to chromatographic systems. In addition, less sample is required for SPE and no solvent disposal problems occur. Both LLE and SPE require appropriate choices of materials (solvents and sorbents). Current developments in water analysis will probably lead to the large-scale introduction of on-line SPE as a basis for validated methods.

2.2 Biological and Soil Samples

Extraction and clean-up of plant and soil samples is complicated by the variations in matrix composition (often characterized by parameters such as percentage of organic matter, sand, and clay). In addition, the composition of the solid samples may negatively influence the extraction efficiency – analytes that have been in prolonged contact with a solid matrix are often desorbed less readily than freshly applied analytes. As a consequence, the recovery of freshly spiked analytes can frequently provide an erroneous impression. The above-mentioned preventive measure of extraction directly after sampling is especially applicable to soil and biological matrices.

Extraction procedures for carbamates (and their transformation products) from plant or soil matrices are mainly hampered by the presence of coextractives. Therefore, a conventional SLE procedure, for instance Soxhlet extraction, blending, or sonication, is usually followed by one or more clean-up steps. These mostly involve column chromatography over a material such as Florisil\(^m\); gel permeation chromatography (GPC) is used for the clean-up of fruit and vegetable extracts. Alternatively, SFE may be applied; it often provides sufficient selectivity to make further clean-up superfluous. The extraction and clean-up of plant and soil samples is discussed separately.

For the determination of N-methylcarbamates, plant material may be treated by SLE using blending, sonication and, less appropriately, Soxhlet extraction. Generally, acetone or mixtures of this solvent with dichloromethane, methanol and/or light petroleum are employed.\(^{(53)}\) Although it has been stated that methanol is the most suitable solvent for the extraction of carbamates from grain, because it extracts up to 15% more of the carbamate residues than acetone or acetonitrile, the presence of coextractives such as the chlorophylls and carotenes makes methanol less attractive.

Separation of the analytes from coextractives by column chromatography over Florisil\(^m\), silica, or alumina produces good results for most carbamates. Multiple desorption is generally applied using different solvents. When employing the oxide-type phases, clean-up recoveries are generally bad (below 50\%) for the more polar compounds, such as aldicarb sulfoxide and sulfone.\(^{(47)}\) In contrast, good recoveries (70–95\%, RSDs 5–9\%) were obtained for the simultaneous determination of aldicarb, its oxide, and sulfone, if these compounds were targeted. The use of an aminopropyl-bonded silica column,\(^{(45,46)}\) with dichloromethane as the extraction
solvent showed good recoveries (85–100%, RSDs 2–4%) for all carbamates tested, although the recoveries of the total pretreatment procedure did not exceed 80% for the polar compounds (aldicarb sulfoxide, butoxcarbim sulfone, 1α-naphthol, and oxamyl). The advantage of aminopropyl-bonded silica over the oxide-type phases is that small extraction volumes can be used and that the number of desorption steps can be kept low. GPC of methanol extracts from blended plant material was reported to give good results with low-pigment material (apples, potatoes), whereas high-pigment materials (cabbage) required a second separation step. Such a second step was realized by connecting a polypropylene minicolumn, packed with 0.5 g Nuchar-Celite™, on-line with the GPC column. Recoveries for both procedures (GPC only or GPC and Nuchar-Celite™) were comparable. Recoveries of 85–100% were obtained for some 10 N-methylcarbamates, whereas the recovery for aldicarb sulfoxide was 50%.

Unfortunately, GPC was only used off-line from the analytical column. High selectivity can be obtained using immunoaffinity precolumns. The application of such a column resulted in the liquid chromatography/ultraviolet spectroscopy (LC/UV) detection (220 nm) of carbofuran from a crude potato extract injected directly on the precolumn. With a C18 bonded-silica phase, overloading of the UV signal was observed, and carbofuran could not be detected. The presence of the coextractives retained on the C18 also caused the suppression of the ion signal in atmospheric pressure chemical ionization (APCI)/MS. This was eliminated when the immunoaffinity phase was used. Although the development of new immunoaffinity precolumns opens a new area within the field of sample pretreatment, up till now the application range of this type of columns is limited to one target compound or a to group of compounds with the same antigen.

Soil can often be conveniently subjected to Soxhlet extraction, using various solvent mixtures and subsequent clean-up over Florisil™. A comparative study showed that acetone–dichloromethane (50:50 v/v) gave the best extraction results for oxamyl, carbaryl, carbofuran, propoxur, 1α-naphthol, chloropropham, and pirimicarb, whereas aldicarb and its oxidation products were initially improved by converting the carbamates into, aC18 bonded-silica phase, overloading of the UV signal was observed, and carbofuran could not be detected. With a C18 bonded-silica phase, overloading of the UV signal was observed, and carbofuran could not be detected. The presence of the coextractives retained on the C18 also caused the suppression of the ion signal in atmospheric pressure chemical ionization (APCI)/MS. This was eliminated when the immunoaffinity phase was used. Although the development of new immunoaffinity precolumns opens a new area within the field of sample pretreatment, up till now the application range of this type of columns is limited to one target compound or a to group of compounds with the same antigen.

Soil can often be conveniently subjected to Soxhlet extraction, using various solvent mixtures and subsequent clean-up over Florisil™. A comparative study showed that acetone–dichloromethane (50:50 v/v) gave the best extraction results for oxamyl, carbaryl, carbofuran, propoxur, 1α-naphthol, chloropropham, and pirimicarb, whereas aldicarb and its oxidation products could successfully be extracted (85–90% recovery) in two successive extractions with acetone–water (40:60 v/v) and methanol–water (50:50 v/v). In contrast to findings for plant material, methanol was shown to extract all carbamates and their degradation products by GC. The reasons for this were the main problems with GC analysis of carbamates, namely thermal decomposition of the analytes on the column and/or in the injector, and insufficient sensitivity of detection. Except for the halogen-containing compounds, such as barban, carbamates in general show a low response to electron-capture detection, flame ionization detection (FID) and thermal sulfur detection (TSD). Detectability was initially improved by converting the carbamates into, for instance, the N-perfluoroacetyl N-perchloroacetyl or pentafluorobenzyl derivatives for electron-capture detection. Later, with the advent of nitrogen/phosphorus detection (NPD) and MS, such derivatization methods became obsolete.

A major advantage of SFE over SLE is that clean-up can be omitted if the extraction parameters are chosen to provide maximum selectivity. SFE with carbon dioxide (typical conditions 50°C, 250 atm, 15 min) has been successfully applied to the extraction of aldicarb and carbaryl from liver samples (recoveries 75–100%, no RSDs reported) and methomyl, methiocarb from fruit and soil samples (recoveries 100%, no RSDs reported).

Despite these promising results, no reports have appeared on SFE treatment of soil samples yet. However, the obvious potential of the method justifies expectations that SFE will be used to a wider extent for carbamate extraction from soil and plant materials in the near future.

### 3 COLUMN CHROMATOGRAPHY

Analytical systems for the determination of carbamates generally involve a column chromatographic step. Initially GC was used, but column LC is now generally preferred. Supercritical fluid chromatography (SFC) was occasionally used as separation technique, but has lost favor during the 1990s. CE has also been used, but the robustness of the technique has still to evolve. In general the separation potential of a particular chromatographic technique is the key issue.

#### 3.1 Gas Chromatography

Many column types, detection techniques, and derivatization reagents have been studied for the determination of carbamates and their degradation products by GC. The reasons for this were the main problems with GC analysis of carbamates, namely thermal decomposition of the analytes on the column and/or in the injector, and insufficient sensitivity of detection. Except for the halogen-containing compounds, such as barban, carbamates in general show a low response to electron-capture detection, flame ionization detection (FID) and thermal sulfur detection (TSD). Detectability was initially improved by converting the carbamates into, for instance, the N-perfluoroacetyl N-perchloroacetyl or pentafluorobenzyl derivatives for electron-capture detection. Later, with the advent of nitrogen/phosphorus detection (NPD) and MS, such derivatization methods became obsolete.
Thermally assisted hydrolysis is a key problem in the GC analysis of carbamates. For example, N-methyl- and N-phenylcarbamates are labile at higher temperatures (>100 °C), whereas N,N-dimethylcarbamates, such as pirimicarb, do not suffer thermal degradation under GC conditions. Thermally assisted hydrolysis may be prevented by the use of special GC systems or by appropriate derivatization. Alternatively, derivatization may be required to yield more volatile derivatives for degradation products such as amino hydroxyypyrimidine compounds (from pirimicarb), because these compounds are not directly amenable to GC. Derivatization and instrument modifications, as a means of prevention of thermal degradation, are discussed next.

In the 1960s and early 1970s, insufficiently deactivated column material caused thermal degradation with a variety of packed-column stationary phases (Carbowax™ 20M, polar; Apiezon N™, nonpolar; SE 30 and QF-1, mixed polarity). Extensive deactivation of the stationary phase and the column support material and the exchange of a glass injection liner by quartz were shown to suppress degradation; however, decomposition tended to increase upon column aging. With the introduction of high-quality deactivated capillary columns (SE-54), thermal degradation is effectively limited to the injector. Recently, this problem was solved by the application of programmed temperature vaporization (PTV) and cold on-column injection for the GC analysis of some thermolabile aryl N-methylcarbamates. (Note that the injector inlets and packing still required deactivation.) Figure 2 shows some chromatograms to illustrate the response dependence of selected carbamates upon the injector type. Despite the fact that contamination of the injection port due to poor clean-up of extracts is known to promote the degradation of carbamates, thermal lability remains an intrinsic property of some carbamates.

Prevention of thermally assisted hydrolysis by derivatization is mainly used for aryl N-methylcarbamates, because these compounds are easily hydrolyzed (to give phenol-type products) and subsequently converted into thermally stable esters. This kind of derivatization may lead to serious overestimation of pesticide levels, because the natural phenol-type degradation products are also derivatized. An alternative derivatization (used for methomyl, an oxime N-methylcarbamate) is hydrolysis to the oxime, subsequent derivatization of which provides a useful conversion into a thermally stable compound. Although derivatization of carbamates is not generally applicable, it may be of use for target compound analysis.

Despite these thermolability problems, some GC/MS methods, using electron ionization (EI) or chemical ionization mass spectrometry (CI/MS), with isobutane as the reagent gas, have been reported for selected compounds. Six GC stationary phases were tested in packed columns, in combination with CI/MS detection, for 32 carbamates. Moderate column temperatures (<185 °C) and short open tubular allowed detection of intact carbamates, except for carbarly (ca. 50% degradation), from spiked soil sample extracts (recoveries 80–112%, RSD 2–9%, 19 carbamates). Packed-column gas chromatography/chemical ionization/mass spectrometry (GC/CI/MS) was used for aldicarb and butocarboxime and their metabolites. Short capillary columns and CI/MS detection were also used to overcome thermolability problems. In both cases, GC with chemical ionization (CI)-triple quadrupole tandem mass spectrometry (MS/MS) detection was used, either to facilitate identification from the CI spectra or to gain selectivity in compensation for loss of chromatographic resolution. No quantitative data are reported in the latter

Figure 2 GC/NPD chromatograms of eight aryl N-methylcarbamates and one N,N-dimethylcarbamate (pirimicarb) using (a) hot splitless, (b) cold on-column and (c) PTV injection. Peak assignment: (1) propoxur, (2) bendiocarb, (3) carbofuran, (4) aminocarb, (5) pirimicarb + ethiofencarb, (6) dioxacarb, (7) carbaryl, (8) methiocarb.
study (on aldicarb, its sulfoxide and sulfone), but the former study specifies absolute limits of detection (LODs) of 0.15 ng (aldicarb nitrile), 0.3 ng (aldicarb) and 1.2 ng (aldicarb oxime) with a linear response from the LOD up to 150 ng and in full-scan mode.

Although some compounds, particularly aldicarb and its sulfoxide and sulfone, and carbaryl, are definitely not amenable to GC; GC with CI/MS detection (and MS/MS) may lead to unequivocal identification and low LODs for some carbamates. In other words, although GC is not the method of choice for the simultaneous determination of a wide variety of thermal labile carbamates and their degradation products, GC with CI/MS detection, possibly combined with derivatization, is a powerful method for target analysis.

3.2 Column Liquid Chromatography

Since the late 1970s LC has become a reliable technique for the separation of all types of carbamates. A 1975 review on the determination of carbamates identified the potential of LC as opposed to GC–LC in that it generally requires less extensive sample pretreatment and enables on-line trace enrichment and sample clean-up. Most importantly no heat is used, which prevents thermal degradation. A comparative study on the separation of carbamates using various normal-phase and reversed-phase modes of operation, and a report on pesticide analysis, then gave LC experimental conditions for many carbamates.

Several reports on the target LC analysis of carbamates and their degradation products have been published since. The quality as well as the nature of the stationary phase are key parameters in most LC studies and both subjects are discussed below.

The presence of free silanol groups may lead to bad peak shapes, especially for polar carbamates and their transformation products. This has been demonstrated for the simultaneous separation of aldicarb, its oxidation products, and their oximes, and for pirimicarb and three of its degradation products. In all cases the use of a buffer in the LC eluent or of a specially end-capped phase was necessary to maintain separation and constant retention times with alkyl-bonded silica phases. Unfortunately, end-capped phases tend to be maintained by using buffered eluents; however, buffered eluents can result in irreproducible retention times for polar carbamates. Regular monitoring of the separation quality and the retention times is therefore recommended.

One study on the use of a wide variety of phases (silica, cyano-bonded, amino-bonded, and C<sub>18</sub>-bonded silica and ether phase-ETH) showed that most compounds could be separated on silica and cyano-bonded silica, whereas amino-bonded silica gave peak broadening, especially for the more polar compounds. In the reversed-phase mode, C<sub>18</sub>-bonded silica gave the best results; no separation of the polar compounds was achieved on ETH. Twenty-two carbamates could be separated on C<sub>18</sub>, using gradient elution (20–60% acetonitrile in water). Furthermore, Zorbax<sup>®</sup> C8 and Zorbax<sup>®</sup> cyano both give insufficient separation – the former case did not produce baseline separation of propoxur, carbofuran, bendiocarb, carbaryl, and 1α-naphthol. Although the cyano phase did not separate aldicarb sulfone and oxamyl (Figure 3b), it was found to be a good phase for the separation of aldicarb and its metabolites. Incomplete separation for pirimicarb and its seven degradation products on polar Hibar RP-8 and amino columns in the reversed-phase mode has also been reported. The LC available phases have a limited capacity for the separation of mixtures containing all carbamates and their degradation products, with problems being encountered especially for polar compounds.

3.3 Capillary Electrophoresis

Despite the many advantages of LC over GC, the inferior separation potential of LC is still a major drawback. Micellar electrokinetic chromatography (MEKC) is a promising technique for the complete separation of all carbamates. Being a unique mode of CE, the separation of these neutral carbamates is realized on the basis of their different affinities to the micellar pseudostationary phase and consequently shows similar behavior as in reversed-phase LC. The difference is the much higher column efficiency in the MEKC system.

However, some important parameters, such as the surfactant concentration, ionic strength, and buffer modifiers still strongly influence the separation power of this technique. The pH, which is important in conventional CE, is of less importance because the carbamates are neutral at pH 7. Moreover, the tendency of carbamates to hydrolyze at higher pH prevents the use of an alkaline buffer. These parameters were investigated extensively by Wu et al. and the resultant method was applied to real-life samples. The optimum sodium dodecyl sulfate (SDS) concentration and the effect of the phosphate buffer (ionic strength) were varied, and the influence of urea and cyclodextrine as additives to the CE buffer were evaluated.

A major advantage in MEKC is the ability to change the capacity factor (k') by changing the SDS concentration. Indeed an increase of the SDS concentration from 20 to 100 mM leads to an increase of k' for all carbamates. The k' increase for aminocarb was so large that, at SDS concentrations of 50 mM, aminocarb started to elute after...
Figure 3 LC chromatogram with fluorescence detection of 10 carbamates and six degradation products, obtained with (a) C₈ and (b) cyan phases, using: 25 cm × 4.6 mm i.d. Zorbax™ column with 6 µm spherical particles; a 30 min linear gradient from 12% to 70% acetonitrile in water; flow rate 1.5 mL min. Peak assignment: (1) aldicarb sulfoxide, (2) aldicarb sulfone, (3) oxamyl, (4) methomyl, (5) 3-hydroxycarbofuran, (6) methiocarb sulfoxide, (7) methiocarb sulfoxide, (8) aldicarb, (9) propoxur, (10) carbofuran, (11) bendiocarb, (12) carbaryl, (13) α-naphthol, (14) landrin, (15) methiocarb, (16) bufencarb.

isoprocarb. For this reason an SDS concentration of 60 mM was considered optimal, even though carbofuran and bendiocarb were coeluting, whereas incomplete separation was still obtained for isoprocarb/aminocarb and carbaryl/trimethacarb. Baseline separation for these four was finally obtained after adjusting the phosphate buffer concentration, and consequently the ionic strength, to 40 mM. Unfortunately the electrophoretic current increased from 25 to 55 µA making the control of the capillary temperature necessary. The separation of carbofuran and bendiocarb was finally achieved after addition of 4 M urea. Another consequence was the reversal of the migration orders of the peakpairs, such as pirimicarb–trimethacarb, isoprocarb–carbaryl, promecarb–methiocarb, isoprocarb–pirimicarb, and carbofuran–propoxur, without the loss of the chromatographic resolution. Also, the addition of hydroxypropyl-β-cyclodextrine resulted in the complete separation of the carbamates and moreover led to a significant reduction of the migration time, making the total analysis time approximately 14 min.

After optimization of all experimental parameters, the reproducibilities of the migration times and peak areas for all carbamates were better than 3 and 8%, respectively. The migration-time value was within 1% when the relative migration time with respect to the first-eluting carbamates was used. These data clearly prove the stability of the system. Nevertheless, the sensitivity using UV detection was still low, typically 200 ppb (only for carbaryl a detection limit of 50 ppb). This drawback was finally overcome by the application the enrichment of the sample with SPE and the increase of the injection volume by stacking. Using ODS-6 cartridges and reducing the sample volume from 50 mL to 100 µL, a 500-fold enrichment of the compounds was achieved. An approximately 5-fold in gain sensitivity was achieved with the positive-polarity stacking mode, bringing the detectability well below 0.1 ppb – this being the requirement for drinking water levels in the EU. Although, these data make this analytical tool a serious candidate for the routine analysis of carbamates, the method was only tested for a test mixture of 15 different carbamates, which is half of the amount used by de Kok et al. Also, no data were reported using environmental samples, such as soil, sediments, groundwater, and other surface waters.

4 LIQUID CHROMATOGRAPHY DETECTION METHODS

Because thermal degradation often occurs in GC, LC is preferred for the separation of thermolabile carbamates in combination with UV, ECD, fluorescence, or MS detection. These techniques differ in terms of analyte detectability and selectivity and
are therefore the most important characteristics of the detection methods discussed below.

4.1 Ultraviolet Detection
Monitoring UV absorbance at properly selected wavelengths and/or recording UV absorption spectra, if diode array detection (DAD) is applied, provides a convenient means of detecting most organic compounds. Many carbamates have a UV absorption maximum in the range of 190–225 nm, and additional maxima at wavelengths between 245 and 280 nm.\[24,89\] It is obvious that multiple-wavelength detection is required to obtain near-maximum sensitivity if a large number of analytes has to be determined. UV detection is best combined with acetonitrile–water mixtures as an eluent, because this allows detection at 195–200 nm (compared with methanol–water at 205–210 nm and tetrahydrofuran–water at >220 nm). Interferences may, of course, be caused by compounds which strongly absorb at 190–220 nm, such as humic acids – in many LC separations a broad hump occurs at low retention times. It has been stated that such interferences may be efficiently trapped by using a cyanopropyl-bonded silica precolumn.\[104\]

Generally speaking, the detection limits obtainable with UV for carbamates are rather average, typically in the lower nanogram range.\[111\] In systems involving on-line trace enrichment this may still be sufficient, such as for surface water analysis with DAD, and will provide some structural information. One should also be aware of problems encountered with complex samples (i.e. insufficient clean-up) which may explain reported differences in carbamate LODs by an order of magnitude when comparing water and soil samples.\[110\] In conclusion, for most sample types of LC, UV detection is suitable for the trace-level determination of carbamates only if it is combined with concentration and/or elaborate clean-up procedures.

4.2 Electrochemical Detection
Despite the inherent sensitivity and selectivity of ECD it has not been as extensively used for LC as might be expected. Problems encountered with the robustness of LC/ECD (liquid chromatography/electrochemical detection) systems (electrode materials, electrode fouling, required experience) are probably the main reasons. Analyte detectability in LC/ECD is strongly influenced by electrode geometry and composition,\[120,122,124\] the LC eluent composition (especially the pH for carbaryl\[120\]), and the presence of electroactive coextractives.

LC/ECD of most aryl N-methylcarbamates and N-phenylcarbamates is easily performed, because these compounds can be oxidized within the available potential range. For example, aminocarb can be detected at a concentration as low as 5 µg L\(^{-1}\).\[120\] The use of a detection potential of about 1.1 V is commonly considered best, although the oxime N-methylcarbamates and some aryl N-methylcarbamates (carbaryl and carbofuran) are electroinactive at this potential. Despite the practical limitations due to the oxidation of water, ECD at 1.9 V has been reported for some N-methylcarbamates (aldicarb and its sulfoxide and sulfone, aminocarb, bendiocarb, carbaryl, methiocarb, and methomyl); unfortunately, the LOD and oxidation potential were specifically mentioned for aminocarb only.\[123\] Alternatively, it has been that aryl N-methylcarbamates, such as carbaryl and carbofuran, can be hydrolyzed on-line to the corresponding phenols, which can be subsequently oxidized at potentials of 0.5–0.8 V.\[125,126\] The general tendency that lower potentials lead to a lower background current and, thus, to better LODs is illustrated by the LODs of 10–35 µg L\(^{-1}\) obtained for some aryl N-methylcarbamates.\[126\] For the rest, it has been observed that LODs for ECD are one order of magnitude better than those obtained with UV detection; however, the reproducibility of ECD is lower than with UV detection, probably due to the slowly increasing contamination of the electrode surfaces referred to above.\[120–126\] From the above it is evident that the main use for LC/ECD is the target analysis of aryl N-methyl- and N-phenylcarbamates.

4.3 Fluorescence Detection
The number of compounds that display native fluorescence is rather restricted. As a consequence, fluorescence monitoring is a selective – and often highly sensitive – method of detection in LC. The selectivity of fluorescence over UV absorption detection is further improved by the fact that two wavelengths (excitation and emission) rather than one (absorption maximum) have to be selected. Compounds which do not exhibit natural fluorescence, such as most carbamates, can only be detected if they are derivatized or otherwise chemically converted into highly fluorescent products.

Fluorimetric detection of carbamates was used in the 1960s, either for direct analysis (e.g. carbaryl) or for the analysis of derivatives (e.g. benomyl).\[129\] The determination of carbamates and their degradation products by a combination of fluorescent labeling and LC was first demonstrated in 1974 (e.g. see Figure 3).\[130\] Precolumn derivatization with dansyl chloride and subsequent normal-phase separation gave detection limits of 0.5–2.5 mg L\(^{-1}\). The method was successfully applied to the determination of carbaryl in potato and corn samples.\[177\] On-line postcolumn derivatization, using o-phthalaldehyde (OPA) as the reagent, was first reported for carbamate analysis in 1978;\[131\] a scheme of the on-line analytical system is given in Figure 4.
The OPA derivatization is preceded by alkaline hydrolysis, to convert the N-methylcarbamates into methylamine, which is subsequently reacted with OPA in the presence of a reducing agent such as 2-mercaptoethanol; the resulting fluorophore is monitored. Several important parameters were studied and the reactions conditions were optimized.\(^{133-136}\) The OPA derivatization finally formed the basis for the reference method (for \(N\)-methylcarbamates) of the US EPA\(^ {138}\) and was commercialized by Perkin-Elmer and the Pickering Laboratories. One main advantage is that OPA itself is completely nonfluorescent, so there is no need to remove the (large) excess of reagent after postcolumn reaction, prior to the actual detection.

The initial set-up of the OPA postcolumn reaction detection system had some disadvantages. Peak broadening occurred, due to the extra dead volume generated by the reaction coils and tee-pieces (the reagent delivery system for the two reaction steps), the hydrolytic conversion was not complete and reproducibility deteriorated over time due to the limited stability of 2-mercaptoethanol. As an alternative, catalytic conversion and heating\(^ {116}\) using a reactor packed with a basic anion-exchange resin\(^ {137-139}\) or magnesium oxide\(^ {140}\) proved successful. Although the rate of hydrolysis of the \(N\)-methylcarbamates differs widely, with temperature optima from 90–100 °C to over 140 °C, LODs as low as 0.1 ng (aldicarb) and 0.85 ng (methiocarb) were reported for the modified system.\(^ {117}\) Miniaturization of the reactor, to achieve compatibility with narrow-bore LC, led to even lower LODs.\(^ {141}\) Photolytically initiated hydrolysis has been introduced, which makes \(N,\,N\)-dialkylcarbamates accessible to reaction with OPA. Photolytic hydrolysis sometimes requires the addition of sensitzers (e.g. acetone) to the eluent to effect the conversion of for example, aldicarb sulphone. Typical LODs of 2.5 µg L\(^{-1}\) were reported.\(^ {142}\) Further optimization of the reactor geometry and of the solvent conditions allowed a one-step conversion of the carbamates into the OPA derivatives,\(^ {133}\) with similar LODs. Finally, the use of 3-mercaptopropionic acid and \(N,\,N\)-dimethyl-2-mercaptoethamine hydrochloride (thiofluor) reagents instead of 2-mercaptoethanol greatly improved reproducibility over a longer time period.\(^ {144}\) The combination of this analytical method with on-line precolumn extraction and SPE-based trace enrichment resulted in detection limits of 0.02–0.03 µg L\(^{-1}\) for all \(N\)-methylcarbamates, and some of their degradation products, in water samples.\(^ {127}\) The application of this method to fruit samples was optimized and validated.\(^ {146}\)

In conclusion, on-line postcolumn OPA derivatization is an excellent tool for the determination of a large number of, though not all (such as \(N\)-phenylcarbamates), carbamates. Being essentially a derivatization-type procedure, it cannot be used for degradation products that do not yield a primary amine upon hydrolysis, nor does it provide structural information. Even so, it is possibly one of the best procedure available today for the trace-level analysis of carbamates.

### 4.4 Mass Spectrometric Detection

MS may be considered as a nearly universal method of detection, as gas-phase ions can be generated from volatile polyaromatic compounds and thermally labile proteins. The high-vacuum system of MS (typically operated at pressures below 1 Pa) was successfully coupled to GC in the late 1960s, and to LC in the early 1980s. Modern GC/MS instruments generally use capillary column GC and direct introduction of the column effluent into the MS source (operating either under EI or CI conditions). Commercially available GC/MS is routinely used and still the method of choice when it comes to identification (typically at microgram per liter levels) and/or of compound quantitation (typically at low microgram per liter levels) of volatile compounds. Since the late 1980, LC/MS has become an proven analytical tool for both qualitative and quantitative biopharmaceutical analysis. The most popular interfaces in the 1980s, TSP (thermospray) and PB (particle beam), have been replaced by the more robust atmospheric pressure ionization (API) techniques, ESP (electrospray) and APCI.

This section discusses the use of LC/MS in combination with TSP, PB, ESP, and APCI, for the determination of carbamates and their degradation products. As regards ionization methods, EI mass spectra of carbamates can only be generated by the PB interface and generally produces the most information to allow unequivocal identification, if necessary with the help of spectrum libraries. CI mass spectra of carbamates give molecular mass and some structural information depending on the applied reagent gas. Spectra from desorption ionization, such as fast atom bombardment (FAB), and from LC/MS-related methods of ionization (TSP, ESP) produce mass spectra with the protonated molecule or adduct ions and do not give any structural information.

The EI/MS of \(N\)-methylcarbamates has been reviewed in a book on environmental analysis.\(^ {148}\) Most \(N\)-monosubstituted carbamates show a molecular ion, \([M]^+\), whereas at least one characteristic fragment ion is usually
observed—the loss of neutral alkyl- or arylisocyanate produces the alcohol radical cation \([M - RNCO]^+\). The EI spectra of the \(N,N\)-dimethylcarbamates, as well as those of most degradation products, cannot be described in general terms.

The positive ion chemical ionization (PCI) mass spectra of carbanates generally show signals of a protonated molecule, \([M + H]^+\), and of the protonated alcohol, \([M + H - RNCO]^+\). The loss of \(\text{CH}_3\text{NCO}\) from protonated \(N\)-methylcarbamates has been investigated in some detail by deuterium labeling and MS/MS experiments. The intensity ratio of the \([M + H]^+\) and \([M + H - RNCO]^+\) signals varies with the reaction gas used. Moreover, some carbanates show adduct ion signals, \([M + \text{NH}_3]^+\), if ammonia is used as the reaction gas. In general, carbanates have a proton affinity close to that of ammonia and protonation should therefore result in good detection sensitivity.

The negative ion chemical ionization (NCI) mass spectra of carbanates have been less well studied. Studies show that molecular anions, \(M^-\), are only observed with some halogen-containing carbanates and that deprotonated molecules have a low abundance or are completely absent. Typical negative fragment ions are the alcoholate ions, \([\text{RO}]^-\), and the carbamic acid anion, (for example \([\text{CH}_3 - \text{NH} - \text{C}(=\text{O}) - \text{O}]^-\) from \(N\)-methylcarbamates). Deprotonation and negative fragment ion formation is inefficient for most carbanates, giving rise to poor detection sensitivity. Deprotonation is potentially more efficient for the degradation products, such as phenol-type compounds, and better sensitivity is to be expected. The general characteristics make NCI less suitable for carbanate analysis.

FAB ionization, as well as LC/MS-related ionization (see below) most often generate mass spectra comparable to those obtained with chemical ionization and typically exhibit the loss of RNCO from \([M + H]^+\) in the positive ion mode. FAB has been applied to the specific detection of benomyl, a compound that is known to decompose to carbendazim under all other MS conditions. FAB ionization, and any of the other desorption-type ionization techniques, is of very limited use for the determination of carbanates, because quantitation is extremely difficult, if not impossible, and because CI produces essentially the same information with fewer practical limitations.

As regards the potential of LC/MS, LC provides adequate separations and MS has the capability of detection and identification of trace amounts of compounds (typically at the nanogram level). This was recognized early in the development of LC/MS interfacing and, consequently, reports have appeared on carbanate analysis using moving belt (MB), direct liquid introduction (DLI), PB, TSP, ESP, and APCI. Recently, PB, TSP, ISP, and APCI were compared in a single study, using eight selected carbanates. The impact of these latter interfacing methods on carbanate analysis is briefly evaluated.

Only the PB interface is capable of (nearly) separating the analyte from the eluent solvents and transferring it to the MS high vacuum. In principle, this allows operation of the mass spectrometer with common MS ionization modes, EI, and CI (eluents independent). However, PB interfacing generally has poor sensitivity (typically at the milligram per liter level) compared with the TSP, ESP, and APCI interfaces. As observed for TSP, the response sensitivity was shown to decrease if more organic modifier is used in the mobile phase. The LC-to-MS transfer efficiency of analytes with PB is concentration dependent and calibration curves can therefore be nonlinear over a large range. It has been claimed, but not convincingly demonstrated, that linear calibration curves at low concentration can be obtained by adding a carrier compound to the LC eluent. The relatively low sensitivity of detection may be improved by sample preconcentration, using on-line SPE, thus allowing LC/PB/MS identification from EI mass spectra at low microgram per liter levels. Another factor complicating the analysis of polar pesticides in general, and carbanates in particular, is the occurrence of thermal degradation during the desolvation process. Complete desolvation of the analyte is achieved by colliding the analyte–solvent cluster against the heated ion-source wall, resulting in an increase of the relative abundance of the fragment ion of \(N\)-methylcarbamates, namely \([M + H - \text{CH}_3\text{NCO}]^+\) in CI and \([M + H - \text{CH}_3\text{NCO}]^+\) in the EI mode. Under conditions of ammonia CI the situation becomes even more complicated, because the intensities of the \([M + H + \text{NH}_3]^+\) and \([M + H]^+\) ions are strongly dependent upon the ammonia pressure in the ion source. It is clear that many parameters need to be optimized before good analytical conditions in terms of response linearity, reproducibility, and detection limits can be obtained. The lack of sensitivity, especially when compared with those of the other three interfaces and the danger of thermal degradation hampering the reproducibility does not make the PB interface the preferred interface for the quantitative analysis of the carbanate pesticides. Nevertheless, it is still a powerful tool for the identification of unknowns.

TSP and APCI typically yield CI-like mass spectra with the protonated solvent and additive ions acting as the reagent gas. In addition, ion–molecule complex formation of the analyte and eluent components is frequently observed. However, the reagent gas pressure and ion source temperature strongly influence the equilibrium of the gas-phase reaction and the mass spectra obtained with
these interfacing methods can differ widely, as illustrated for carbofuran in Table 3. The LC eluent composition, source temperature, source pressure, flow-rate, and ion source tuning should be optimized to produce maximum sensitivity. Optimization of the experimental conditions often requires compromises, because most parameters are interdependent and different parameter optima for different compounds are most often obtained.

TSP has been the most popular interfacing technique, especially for the analysis of carbamate pesticides. The TSP interface places some restrictions on the chromatographic system (non-volatile salts or reagents should not be present), but is effective in the presence of an ionogenic compound (typically ammonium acetate). This additive is required to induce proton transfer reactions during and after evaporation, thus causing the formation of detectable ions. In the PCI mode, protonation and ammoniation of the analyte are typically observed (giving rise to $[M + N H_4]^+$ and $[M + N H_4 - CH_3NCO]^{+}$ ions, respectively). In the NCI mode, electron capture, deprotonation, and acetate adduct formation are commonly observed (giving rise to $M^-$, $[M - H]^-$ and $[M + CH_3COO]^{-}$ ions, respectively).

Most carbamates are amenable to TSP/MS detection, despite the thermal character of the desolvation process. Detection of carbamates is generally most efficient in the PCI mode, whereas the NCI mode is best for detection of halogenated carbamates and hydroxyl-containing degradation products. The performance of TSP/MS is improved, at least for carbamates, if the ionization is assisted either by using a discharge or by a filament. Under all TSP conditions the carbamates tend to fragment by losing of CH$_3$NCO from protonated molecular ions or even from adduct ions. More specific fragmentation may be obtained from MS/MS experiments, such as with triple quadrupole MS, but MS/MS techniques generally cause the analyte detectability to deteriorate. Furthermore, many carbamates tend to form adduct ions, with ammonia or with solvent molecules, or (apparently) with strange ions, such as $[M + 32]^+$ and $[M + 59]^+$. Although fragmentation may provide limited means of structure attribution, the occurrence of odd and adduct ions may hamper identification. Moreover, fragmentation, odd ion, and adduct ion formation represent side reactions which may be undesirable from the point of view of quantitative analysis.

The parameters that characterize TSP conditions have been studied extensively for carbamates. Instrument parameters, specifically the geometry of the TSP interface and the MS source, are (generally) invariant parameters, which may have a major influence. With filament or discharge-assisted ionization and PCI detection being the most effective, ion source temperature, vaporizer temperature, and eluent composition are important optimizable parameters, which may exhibit different optima for different instruments.

High source temperatures (up to 300°C) lead to more intense fragment ion signals ($[M + H - CH_3NCO]^+$ and $[M + NH_4 - CH_3NCO]^{+}$) with asulam, carbaryl, carbofuran, oxamyl, chloropropham, desmedipham, and phenmedipham. This increase in intensity is probably due to thermal dissociation by loss of CH$_3$NCO, with subsequent protonation (ammoniation) of the alcohol-type reaction product, because near-thermal equilibration conditions occur inside the source under the high pressure applied (estimated at <13.3 Pa). Hence, the source temperature for detection of carbamates, as such, has a maximum.

The vaporizer temperature may also induce thermal dissociation, as shown for methiocarb. This temperature is the more critical because adequate evaporation and stable ion currents are only obtained above a certain minimum temperature. Thermal dissociation is easily established by monitoring fragment and protonated molecule currents over a range of temperatures. The vaporizer temperature may well influence the degree of desolvation of the analytes, but no effects on adduct ion intensities have been reported.

The LC eluent composition affects the efficiency of detection, because it primarily determines the possibility for adduct ion formation, for protonation, and for fragmentation. Moreover, the eluent components influence initial vapor formation and different eluents therefore generally require different vaporizer temperatures.

The most widely used LC/MS coupling techniques are the API interfaces, ESP, ISP and the HN. The latter is better known as the APCI interface. They provide superior performance in terms of detectability, reproducibility, and response linearity over TSP and PB. The major drawback of the original ESP interface was the limited flow rate, typically 2–10 µL min$^{-1}$, making postcolumn splitting of the eluents necessary. In order to increase the applicable flow rate, ultrasonically, thermally,

and pneumatically\textsuperscript{(199)} assisted ESP interfaces have been developed. The latter type can be used with flow rates of up to 1 mL min\textsuperscript{−1} and has been applied to the determination of carbamates.\textsuperscript{(184)} Nevertheless, optimal sensitivity for the carbamates is obtained at flow rates of approximately 0.3 mL min\textsuperscript{−1},\textsuperscript{(185,186)} and postcolumn splitting still remains an option, because the interface design is responsible for the concentration dependence of the MS signal. LODs are typically in the low-picogram range,\textsuperscript{(186)} making possible the determination of carbamates at 0.1 µg L\textsuperscript{−1} in tap water without any sample preconcentration (see Figure 5). Moreover, the reproducibility of ISP is far better than TSP. The reproducibility of ISP is strongly dependent on the stability of the ion evaporation (IEV) and the desolvation processes in the ion source. Complete or stable desolvation in the API source is achieved by optimizing the counter-current nitrogen gas flow and the voltage on the sampling cone of the MS. At high cone voltages, collisionally induced dissociation can take place generating fragment ions, which facilitates structural identification (see Figure 6). However, high cone voltages can cause dispersion of the ions (the intensity of the protonated molecule is also reduced due to the fragmentation process) lowering the signal intensity and increasing the chemical noise. The interface was successfully applied to identify the carbamates carbofuran and methiocarb together with their degradation products in groundwater.\textsuperscript{(187)}

Both parameters are also of importance with the HN. With this interface the eluent is evaporated by heat-assisted pneumatic nebulization, allowing the use of conventional LC systems with eluent flow rates of 1–2 mL min\textsuperscript{−1}. Despite heating the probe to temperatures of typically 500°C, achieving complete desolvation, no thermal degradation of the carbamates was observed.\textsuperscript{(166)} The counter-current gas flow and the cone voltage show a comparable behavior to that observed with the ISP interface, and ions are formed by gas-phase reaction at atmospheric pressure of the desolved analytes with a reagent gas, a process better known as APCI. By changing the eluent composition, and consequently the reagent gas, fragment ions can be generated, making structural confirmation possible. Selectivity can also be influenced by the choice of the reagent gas. However, before ionization, the compound is evaporated to the gas phase, which makes the HN interface unsuitable for truly nonvolatile compounds, such as azo dyes. Sensitivity is good with detection limits of typically 2–750 ng L\textsuperscript{−1} using

analytical columns of a few centimeters and the selected ion mode.\(^{(105)}\)

Regarding its sensitivity, reproducibility, and dynamic range, APCI can be considered as the method of choice\(^{(166)}\) for the qualitative and quantitative determination of carbamates and other less polar compounds, whereas ESP and ISP are best suited for polar species or molecules with acidic (phenoxycacids, sulfonated surfactants) or basic groups. Application of proper off- or on-line preconcentration techniques, in combination with TSP and PB, will make the determination of carbamates at concentration levels of 0.1 \(\mu\)g L\(^{-1}\) possible. Nevertheless, the application of these interfaces is mainly hampered by thermal degradation, which is responsible for poor reproducibility.

5 CONCLUSIONS

Carbamate pesticides and their transformation products can be determined in various matrices at low and even sub microgram per liter levels. Table 4 gives typical LODs for oxime and aryl N-methylcarbamates in aqueous samples. It should be noted that the methods of sample preparation and of separation in the quoted papers differ widely, and that the compound classes selected are not representative for all carbamates. Moreover, the listed detection limits can be decreased up to three order of magnitude when off- or on-line preconcentration techniques are applied.

Isolation of carbamates from water samples is preferably carried out by SPE, whereas SLE still is the method of choice for biological materials and soil. With SFE good results are obtained for the extraction of analytes from biological materials and soil, but more research is required. LC is the most applied separation technique for the determination of the carbamate pesticides, preferably performed on C\(_3\)- or cyanopropyl-bonded silica with methanol–water or acetonitrile–water mixtures as eluent. GC is still a good alternative with PTV. With this technique thermal degradation of the carbamates in the injector is prevented.

UV is an universal detection technique and therefore the conventional choice when all carbamates need to be determined. The lack of sensitivity can be compensated by the application of on-line preconcentration techniques, resulting in the determination of the carbamates at low microgram per liter levels. Even more sensitivity and selectivity is achieved by subjecting them on-line, to first, hydrolysis and then reaction with OPA, to form a highly fluorescent product, making fluorescence detection the method of choice for the quantitative analysis of \(N\)-methyl and carbamoyl carbamate pesticides. Comparable detection limits are obtained with MS detection, which is a sensitive and universal detector. Combination with on-line preconcentration, which may easily improve analyte detectability by up to 1000-fold, provides the means to confirm, and sometimes unambiguously identify, all carbamates and their degradation products.

LC/PB/MS has a good identification potential that requires substantial preconcentration if the analytes have to be detected at low levels.\(^{(201,202)}\) However, many parameters influence sensitivity and reproducibility, making it and difficult tool to handle. LC/TSP/MS in combination with preconcentration has been successfully applied for many years. Nevertheless, problems comparable with those of the PB type of interface have been encountered, hampering quantitative analysis.

The reports on API-type interfaces show that LC/APCI/MS and LC/ISP/MS are the main competitors of the former interfacing techniques with respect to sensitivity and identification potential.\(^{(166)}\) No evidence of thermal degradation is observed with either API interface. Consequently, the requirements for multiresidue analysis of carbamate and carbamoyloxime insecticides at trace levels (\(<0.1\ \mu\)g L\(^{-1}\)) are easily met by the combination of LC/API/MS and preconcentration techniques (with sample volumes of less than 50 mL), be it off- or on-line.

1 Introduction

Over 25% of pesticides and other toxic organic pollutants are chiral, as are 19 of the 209 polychlorinated biphenyl (PCB) congeners; that is, they exist in two forms; the crystal face of each form was the mirror image of the other. This was the first observation of the natural phenomenon known as chirality, which shortly gained recognition as a critical factor in biological chemistry. Chiral compounds are those that contain at least one center of asymmetry, which results in the occurrence of mirror image isomers called enantiomers. There are two main types of asymmetry – tetrahedral asymmetry about sp\(^3\)-bonded carbon or phosphorus atoms, in which case each of the four attached groups must be different, and axial asymmetry with sterically restricted rotation about, for example, a carbon–carbon or nitrogen–carbon bond (Scheme 1). Mirror image isomers resulting from axial asymmetry are called atropisomers. A more general name for mirror image isomers is optical isomers, because such isomers differ only in their direction of rotation of plane-polarized light. There are no other chemical or physical differences except for one critical exception – each enantiomer of a chiral compound reacts at a different rate with each enantiomer of another chiral molecule. As complex biochemical molecules are generally chiral, and usually exist as only one of the possible enantiomers, the enantiomers of active substrates such as pharmaceuticals and pesticides react with such biochemicals at different rates and, hence, the great recent interest in chiral drugs, and now in chiral pesticides.

A racemate, or racemic mixture, is an equal mixture of the enantiomers of a chiral compound; thus, a racemate is itself not optically active. Enantiomers were formerly designated as (d) and (l), for dextrorotatory and levorotatory, corresponding to the rotation of the plane of light to the right or to the left, respectively; this has been superseded by (+) and (−). The direction of rotation of light is incidental to the absolute configuration of the molecule, which is the actual arrangement in space of the groups around the asymmetric center and is the real determinant of the molecule’s chiral properties (see the
A complete description of a chiral molecule, or of an enantiomer, entails notation of both the absolute configuration (if known) and the direction of light rotation, such as \((R)-(+)\) and \((S)-(-)\). It is fairly common, however, to simply refer to a particular enantiomer as the \((-)\) or \((+)-\) species to distinguish one from the other. More information about chirality is given in the comprehensive treatise on the subject by Eliel et al.\(^1\)

The same factors that make chirality so important in the interactions of drugs with complex biological materials in the human body are also effective in pesticide interactions with receptors. Until the mid to late 1980s, most chiral drugs were marketed as the racemate, such as is produced in typical synthetic processes. However, there are many examples showing that single-enantiomer drugs are more effective or less harmful than the racemic mixture.\(^2,3\) The \((+)-\) enantiomer of ibuprofen, the raceme of which is used as an analgesic and muscle relaxant, is as effective as the racemate, without the side effects. Only the \((-)-\) enantiomers of barbiturates have the desired narcotic effects; the \((+)-\) enantiomers sometimes have convulsive properties. Methadone is used in drug-dependence treatment as a substitute for more harmful drugs such as cocaine; \((-)-\) methadone effects last for 72 h, whereas racemic methadone effects last for only 24 h. Racemic retalin, used in treatment of hyperactivity in children, has side effects of insomnia and appetite suppression; the \((2R,3R)-\) enantiomer avoids these side effects. With US Food and Drug Agency approval and encouragement to use the effective enantiomer, the production and marketing of single-isomer drugs has become an extremely important business. Of the 100 top-selling drugs worldwide, 50 are now single enantiomers with sales of $42.8 billion of the $85.2 billion total for the 100.\(^3\)

Chirality in the environment has become recognized as an important phenomenon since the late 1980s,\(^4-6\) and related research has centered on the need to understand the environmental fate and effects of pesticides and PCBs. As with drugs, chiral pesticides are usually enantioselектив in their interactions with naturally occurring biological molecules; that is, one enantiomer will react faster than the other. The processes of microbial and other enzymatically catalyzed transformations, uptake into plants and animals, translocation across protein membranes, and metabolism in various organs are all likely to be enantioselектив. This can lead to enantioselектив occurrences in, for example, soils where enantioselектив microbial degradation has depleted one enantiomer faster than the other. It is important to remember, however, that abiotic processes are not inherently enantioselектив. Each enantiomer of a chiral compound behaves identically in reactions involving abiotic hydrolysis, photolysis, reduction, oxidation, etc. because it is not reacting with other chiral molecules or systems.

**Example in Scheme 1.** The absolute configuration about a chiral center is designated \((R)\) or \((S)\) (sometimes \(D\) and \(L\)) according to established rules of spatial arrangement. If a molecule has more than one center of asymmetry, there will exist more than two enantiomers, and it is necessary to designate the absolute configuration of each for a complete description of the molecule’s chirality.

**Scheme 1** Structures of representative chiral and achiral pesticides. Notice: (1) the absolute configuration of the dichlorprop enantiomers; (2) that organophosphorus compounds can be chiral because of asymmetry about a carbon atom or the phosphorus atom; and (3) the two centers of asymmetry in metolachlor, one because of asymmetry about a carbon atom and the other because of sterically restricted rotation about a nitrogen to carbon bond. 2,4-D, 2,4-dichlorophenoxy acetic acid.

Several examples of enantioselectivity in the environment have been published in the scientific literature, mostly in the mid to late 1990s. For example, it was shown in 1993 that there exists considerable diversity in the enantioselectivity of various enzymatic degradation pathways for \( \alpha \)-hexachlorocyclohexane (\( \alpha \)-HCH). Research in 1994 on the occurrence of toxaphene congeners in tissues of aquatic vertebrates showed enantioselectivity for several of the chiral congeners. In 1995, researchers reported the rapid enantioselective degradation of several acetamide herbicides. In 1996, experiments showed that 1,1-dichloro-2-(o-chlorophenyl)-2-(p-chlorophenyl) ethane (\( o.p' \)-DDD) residues in about 20 whole-body samples from three fish species were enriched in the (\( - \))-enantiomer. Most recently, the enantio-selective degradation of 1,1,1-trichloro-2-(o-chlorophenyl)-2-(p-chlorophenyl) ethane (\( o.p' \)-DDT), \( c.i.s \) and \( t.r.a.n.s \)-chlordane, and heptochlor epoxide was demonstrated to occur in soils in the US cornbelt. Finally, the enantioselective occurrence of the methylsulfonyl metabolites of several chiral PCB congeners was measured in polar bears and seals.

In addition to these fate processes, the mode of action and effects of chiral pesticides and other anthropogenic compounds are generally enantioselective. For example, the (\( R \)) enantiomers of dichlorprop and mecoprop, important phenoxypropionic acid herbicides, are herbicidally active, whereas the \( (S) \) enantiomers are ineffective; however, the \( (S) \) enantiomers of metolachlor are the most active of its four enantiomers. Finally, the (\( - \)) enantiomer of \( o.p' \)-DDT is much more active in endocrine disrupter tests than the (\( + \)) enantiomer, whereas both enantiomers of \( o.p' \)-DDD have low activity. More information on the synthesis and mode of action of enantiomers of chiral pesticides is given by Tombo and Belluš.

Many pesticides and other environmental pollutants are chiral – 25% of the pesticides manufactured in 1995 were chiral compounds. However, chiral pesticides are almost always manufactured and formulated as their racemic mixtures. Some individual chiral pesticides, as well as some pesticide classes containing several chiral members, are:

- phenoxypropionic acid herbicides
- \( o.p' \)-DDT and \( o.p' \)-DDD
- \( \alpha \)-HCH
- \( c.i.s \) and \( t.r.a.n.s \)-chlordane
- many toxaphene congeners
- 19 of the 209 PCB congeners (atropisomers)
- imidazolinone herbicides
- acetamide herbicides
- pyrethroid pesticides
- organophosphorus pesticides.

Scheme 1 gives the structures of some chiral pesticides, with some achiral compounds for comparison.

2 ANALYSIS OF CHIRAL PESTICIDES AND POLYCHLORINATED BIPHENYLS

Samples for analysis of chiral pesticides and PCBs may include air, surface water, groundwater, drinking water, bottom sediments, soils, and a variety of biological species. In the analysis of such samples, whether environmental or biological, the main objective is usually to determine the enantiomeric ratio (ER) of the chiral analyte(s). The first goal is the separation of the enantiomers; the second is the separation of both enantiomers from other sample components. These samples differ from conventional complex environmental or biological samples only in that special techniques and/or reagents are employed to achieve final separation of the enantiomers. An overview of chiral separations of pesticides is available. Preparation of samples for instrumental analysis involves the same basic steps as required for any sample: extraction of the analyte(s) from the bulk matrix and clean-up of the extract to remove interfering materials. None of these operations can affect the ER of the chiral analyte because all such processes are abiotic and nonchiral, unless specifically designed for enantioselectivity (such as with chiral adsorbents in column chromatography).

Conventional analytical instruments are generally used for chiral analysis of prepared environmental and biological samples. Capillary GC and HPLC are by far the most commonly used instruments for chiral analysis of pesticides and PCBs, although CE is becoming more important because of its demonstrated effectiveness in separating drug enantiomers. Each of these instrumental techniques is addressed in the following sections, with illustrations of enantiomer separations.

2.1 Chiral Separations by Gas Chromatography

As in conventional capillary GC, volatile and semivolatile chiral analytes, including the PCB atropisomers and many pesticides, are separated as their vapors are passed across a stationary liquid phase. Separation of these analytes is based on their preferential partitioning between the gas
PESTICIDES

and liquid phases; however, separation of the enantiomers requires complementary, specific, steric interactions. This is usually accomplished by preferential association between each enantiomer and a chiral component of the liquid phase, to form two transient diastereomers that have different properties, and so are separable. Most of these chiral components, and the great majority of those used for chiral pesticide analysis, are CDs, which are either dissolved in a conventional liquid phase, usually a polysiloxane, or chemically linked to the polysiloxane backbone for added stability. Even more stable columns are now available; these have the chemically linked phases bonded to the fused silica column surface.

The CDs are cyclic molecules composed of six, seven, or eight linked carbohydrate moieties called α-, β-, or γ-CDs, respectively; these cyclic structures are in the shape of a truncated cone (Scheme 2). Because each of the enantiomers of a chiral compound has a different spatial configuration, there is often a preferred fit into the cone so that the two complexes formed between the two enantiomers and the CD are of different strengths. In addition, each carbohydrate moiety contains one primary and two secondary hydroxyl groups, any of which may form hydrogen bonds with the enantiomers; this is a secondary complexation mechanism that often enhances separation. Various derivatives of these CDs have been developed since the mid 1990s. The most common of these result from methylation of two or three of the hydroxyl groups on each carbohydrate moiety. Other derivatives include combinations of O-pentyl, O-acetyl, O-(S)-2-hydroxypropyl, and O-tert-butyldimethylsilyl substituents. Thus, there is currently available such a variety of CD-based capillary columns that the enantiomers of most gas chromatographable chiral compounds can be separated.

Vetter and Schurig published a comprehensive article about GC analysis of chiral organochlorine

Scheme 2 Molecular model of α-CD (above) and the ring structures of α-, β-, and γ-CD.
CHIRAL PESTICIDES AND PCB CONGENERS IN ENVIRONMENTAL SAMPLES, ANALYSIS OF

compounds, emphasizing separation by CD-based chiral phases and including examples of chiral separations. Other examples of chiral GC separations, including the enantiomers of cis- and trans-chlordane, o,p'-DDT, and a pair of PCB atropisomers, are given in Figure 1.

Detection of enantiomers after GC separation can be by any of the conventional GC detectors, depending on the properties of the chiral analyte. These detectors include mass spectrometers and infrared spectrophotometers for compound detection and identification.

2.2 Chiral Separations by High-performance Liquid Chromatography

The method of choice for chiral compounds that are not gas chromatographable is HPLC. Such compounds are ionic or polar and/or heat labile and include many pesticides and their metabolites. The HPLC separations are based on liquid–solid partitioning which, for chiral separations, may involve several mechanisms of complexation between solute (analyte) and a chiral stationary phase in an otherwise conventional column; separations may be by the reversed phase or normal phase mode. According to a common classification system, these chiral stationary phases are divided into five basic types, depending on the complexation mechanism. These mechanisms may include hydrogen bonding, dipole–dipole interactions, π–π interactions, steric hindrance, ligand exchange with metal complexes, and formation of inclusion complexes within chiral cavities. In most cases, the chiral phase is covalently bound to the silica support to achieve greater column stability. Type I chiral stationary phases include the popular Pirkle phases, which are based on π–π and other attractive interactions. Type III phases include the important phases based on CDs (section 2.1), which are usually covalently bonded to the silica through their primary hydroxyl groups. More recently, a variety of derivatives of these, made by reacting some of the secondary hydroxyl groups, have become commercially available. A major work on chiral separations by HPLC gives more information on chiral columns.19

Detection of enantiomers is usually with conventional HPLC detectors; most often these are ultraviolet/visible (UV/VIS) filter photometric or UV/VIS diode array detectors. Fluorescence detectors provide greatly increased sensitivity for compounds that fluoresce or can be derivatized with a fluorescent reagent. Contrary to GC, there are commercially available HPLC detectors that can measure the optical activity of an eluting compound. These involve the principle of polarimetry, a technique that has been used for almost 150 years for the
measurement of optical activity. Modern HPLC detectors of this type use a plane-polarized laser beam that rotates left or right in the presence of an optically active compound, be it an enantiomer or a nonracemic mixture of unseparated enantiomers. Laser-based polarimetric HPLC detectors can measure as little as 12 ng of sample. The simultaneous measurement of absorbance and optical rotation during the resolution of chiral substances on a chiral HPLC column makes possible the determination of the enantiomer composition in spite of extensive peak overlap.\(^{(20)}\)

Figure 2 gives examples of enantiomeric separations by HPLC. Included are methamidophos, which requires a low temperature for separation on the particular column used, and \(o,p'\)-methoxychlor, which also separates better at lower temperatures. Although resolution of enantiomers usually increases with decreasing temperature, lower temperatures diminish column efficiency.\(^{(19)}\) The enantiomers of malathion, which is not asymmetric about the phosphorus atom but does contain an asymmetric carbon, are separated by 5.5 min at 25°C.

Preparative HPLC is the primary technique used for separation and collection of adequate amounts of the enantiomers of a pesticide for the determination of optical rotation, absolute configuration, biological activity and/or toxicity of the respective enantiomers, as well as for studies of their environmental fate. For example, a permethylated \(\gamma\)-CD column was used to separate and collect about 50 \(\mu\)g of each enantiomer of \(o,p'\)-DDT and \(o,p'\)-DDD for determination.

Figure 2 Enantiomeric separations by HPLC using a Chiracel\textsuperscript{®} OJ column (Chiral Technologies, Inc., Exton, PA, USA): (a) \(o,p'\)-methoxychlor separates more efficiently at lower temperatures; (b) methamidophos requires a low temperature for separation; (c) malathion separates very efficiently at 25°C. (This figure is supplied courtesy of the US Environmental Protection Agency and Chiral Technologies, Inc.)
of optical rotation (using a polarimetric detector during separation) and absolute configuration (by subsequent chemical means). More recently, Type II chiral HPLC columns were used to separate 200–300 mg of each enantiomer of these two compounds, as well as the enantiomers of dichlorprop acid, dichlorprop methyl ester ruelene, and \( o,p'-\)methoxychlor, for subsequent testing of their respective endocrine-disrupting activities.

### 2.3 Chiral Separations by Capillary Electrophoresis

Commercial CE instruments have been available only since the mid-1980s, but have made a great impact in the drug industry in analysis of polar, especially ionizable, pharmaceutical products, including chiral products. The fair to high water solubility of such compounds lend them to the particular advantages of capillary zone electrophoresis (CZE), the most common mode of CE. In CZE, an electric current flowing through a fused silica capillary column creates an electro-osmotic flow (EOF) of the aqueous buffer, or carrier electrolyte, which generally moves toward the cathode; this flow also carries along the analytes. The pH of the buffer is adjusted in accordance with the \( pK_a \) of the analyte to create either a positive or negative charge on the analyte, so that it is attracted to either the cathode or the anode. However, the electro-osmotic flow is generally strong enough to eventually move both cations and then anions toward the

![Figure 3](image)

**Figure 3** Enantiomeric separations by CE: (a) ruelene and dialifos (dialifor) by the MEKC mode of CE using hydroxypropyl-\( \beta \)-CD and \( \gamma \)-CD chiral selectors, respectively; (b) three phenoxy acid herbicides by the CZE mode using trimethyl-\( \beta \)-CD (notice that 2,4-D is not chiral); (c) imazaquin by CZE using dimethyl-\( \beta \)-CD. (This figure is supplied courtesy of the US Environmental Protection Agency.)
cathode. This movement carries the analytes through the detector window, which is simply a small section of the column, close to the anode, with the protective polyimide coating removed.\(^{(22)}\)

Detection in CE analysis is by UV/VIS filter photometers or diode array detectors. Because the detector cell is in the column, the path length is very short, only 25–100\(\mu\)m, so that sensitivity is proportionately less than with a UV/VIS HPLC detector. However, excellent sensitivity for fluorescent compounds or fluorescent derivatives can be achieved using a laser-induced fluorescence detector. In addition, columns widened to about 1 mm just at the detector window and columns arranged in a Z configuration to provide an extended cell pathlength at the window are available and these provide moderate sensitivity improvements. Finally, various types of electrochemical detectors that provide increased sensitivity and selectivity have been devised, but none of these are commercially available.

As is the case with pharmaceutical products, CZE is a good technique for analysis of ionizable pesticides. There are several classes of these for which CZE methods have been developed, including sulfonylureas, imidazolinones, triazines, and phenoxyacids. Many pesticides are not ionizable, of course, so cannot be analyzed by CZE—they simply move with the EOF without separating from one another. Micellar electrokinetic chromatography (MEKC) is a mode of CE designed for the analysis of nonionic compounds. In this mode, a surfactant, such as sodium dodecyl sulfate, is added to the CE buffer to create charged micelles. These micelles interact with the nonionic analytes (and often the ionic ones), resulting in a charged micelle-analyte complex that moves with the electric current, just as in CZE. The micelles act as a pseudostationary phase to provide the chromatographic part of the separation.

Separation of the enantiomers of chiral compounds by CE is simpler, faster, and often more efficient than with HPLC or GC. With CE, the appropriate chiral reagent (chiral selector) is simply added to the carrier electrolyte. In CZE, complexation of the enantiomers with the selector occurs in the aqueous buffer solution and, if the reaction is selective (complexation constants differ), enantiomeric separation occurs. For example, the enantiomers of three chiral phenoxy acid herbicides were separated by CZE using trimethyl-\(\beta\)-CD as the chiral selector (Figure 3).\(^{(23)}\) In MEKC, complexation also occurs, but the neutral complexes of both enantiomers are then incorporated into the micelle for electrophoresis to occur. Schmitt et al. accomplished the enantiomeric separation of a variety of neutral chiral pesticides using MEKC with CD chiral selectors.\(^{(24)}\)

Chiral selectors for CE are usually similar to the CDs used for chiral separations in HPLC or GC, except they are used in their neat chemical form rather than being part of a solid or liquid phase in a column. Most CDs are water soluble at the concentrations required for optimum enantiomer separation. Organic modifiers, usually methanol or acetonitrile, are often added to

---

Figure 4 (a) Enantioselective microbial degradation of dichlorprop (acid) followed by CE using trimethyl-\(\beta\)-CD as the chiral selector. (b) Enantioselective microbial degradation of methyl dichlorprop followed by GC using a dimethyl-\(\beta\)-CD chiral column; numbers above peaks are retention times. (This figure is supplied courtesy of the US Environmental Protection Agency.)
the CZE or MEKC electrolyte to enhance separation; these modifiers also enhance the solubility of the CD as well as hydrophobic analytes. Sulfated ionic CDs have been developed that are not only more water soluble, but also eliminate the need for micelles; they selectively complex with enantiomers of both neutral and ionic analytes to produce ionic species for direct electrophoresis.\(^{(25)}\)

Figure 3 shows MEKC enantiomeric separation of two organophosphorus pesticides: ruelene, which requires the chiral selector hydroxypropyl-\(\beta\)-CD for separation, is chiral because of asymmetry about the phosphorus atom; dialifos, requiring \(\gamma\)-CD, contains an asymmetric carbon. Figure 3 also illustrates CZE enantiomeric separations of an imidazolinone herbicide and three phenoxypropionic acid herbicides.

### 3 Applications of Enantiomeric Separations to the Environmental Chemistry of Pesticides and Polychlorinated Biphenyls

The illustrations in the preceding section show successful enantiomeric separations of pesticide and PCB standards. The following figures illustrate the usefulness of these separation techniques in the study of environmental processes and the analysis of real samples that relate to problems in environmental chemistry.

Figure 4 shows the enantioselective microbiological degradation of the herbicide dichlorprop (2,4-dichlorophenoxy-2-propionic acid) in soil with time.\(^{(26)}\)

![chemical structure](image)

**Figure 5** Acid hydrolysis of ruelene at pH 2.5 followed by CE in the MEKC mode using hydroxypropyl-\(\beta\)-CD as the chiral selector. Notice the formation of the product and the lack of enantioselectivity (equal enantiomer concentrations) in the loss of ruelene because this is an abiotic reaction. (This figure is supplied courtesy of the US Environmental Protection Agency.) EOF, electro-osmotic flow.
This herbicide is a component of Foxtril, a commercial formulation of herbicides. The $S$-(-)-enantiomer, with a half life of 4.4 days in this soil environment, degrades faster than the $R$-(+)-enantiomer, which has a half life of 8.7 days. Separation was by CZE, using heptakis (2,3,6-tri-O-methyl)-$\beta$-CD as the chiral selector.

The methyl ester of dichlorprop was used as a probe to assess the enantioselective activity of microbial populations in a variety of soil samples that had received different treatments. For example, exposure of this herbicide to one organic-rich soil resulted in complete degradation of the $(-)$-enantiomer in less than 48h, as shown in Figure 4. This degradation process was followed by GC, using a dimethyl-$\beta$-CD column.

Figure 5 includes MEKC electropherograms of the organophosphorus pesticide ruelene (or crufomate, 4-t-buty1-2-chlorophenylmethyl N-methyl phosphoramidate) before and during acid hydrolysis at pH 2.5. Enantioselective separation of ruelene is achieved by the addition of hydroxypropyl-$\beta$-CD to the MEKC buffer. After 19.5 h, most of the ruelene has hydrolyzed and a product peak, thought to be the phosphate ester resulting from hydrolysis of the P-N bond, is evident. (This product is chiral, but the particular chiral selector used was not appropriate for its enantiomeric separation.) A third electropherogram at 45h shows the ruelene to be completely degraded; the half-life of this reaction was measured in this way as 16.4 h. It is obvious that the degradation was not enantioselective, which is as expected because this is an abiotic reaction.

**Figure 6** GC traces of the atropisomers of PCB 91 showing enantioselectivity in (a) sediment and (b) biota samples from Lake Hartwell. Increase in sample number (G27 to G46) corresponds to increase in distance from PCB spill. Separation is by chiral GC using a permethylated-$\beta$-CD bonded to a DB-5 stationary phase. (This figure is supplied courtesy of the US Environmental Protection Agency.)

PCBs are extremely persistent in the environment and are known to bioaccumulate in various animal species. Figure 6 shows GC traces of the enantiomers of PCB 91, one of the chiral congeners, in a series of sediment samples from Lake Hartwell, South Carolina, USA. A mixture of Aroclors, which are PCB commercial formulations, was accidentally spilled into the lake from a manufacturing facility some 25 years ago and has accumulated in the sediments. The chromatograms were obtained using a column containing permethylated-$\beta$-CD bonded to a DB-5 stationary phase. The data indicate that PCB 91 has degraded enantioselectively; the degree of selectivity decreasing with distance away from the spill as the Aroclor concentration decreases below a threshold necessary for microbial degradation. Figure 6 also depicts the high degree of enantioselectivity of PCB 91 that had accumulated in bass and bluegill fish and in a water snake from Lake Hartwell. Apparently, either bioaccumulation or metabolism in these aquatic species is enantioselective.

**ACKNOWLEDGMENTS**

Appreciation is expressed to Charles Wong, Jimmy Avants and Darrell Rennels for the examples of GC separations shown in Figure 1; to Jackson Ellington and John Evans for the HPLC examples in Figure 2; to Jimmy Avants and Tracy Cash for the CE separation of Imazaquin shown in Figure 3; and to Philippe Schmitt for assistance with the separations and kinetic data illustrated in Figures 3 and 4. Alton Wittemore and Glenn Chapman were responsible for the methyl dichlorprop data and GC separation in Figure 4; Lorrie Howell performed most of the kinetic work depicted in Figure 5; and Charles Wong produced the GC data of Figure 6. These persons are all associated with the US Environmental Protection Agency Laboratory in Athens, Georgia, USA, except for Philippe Schmitt, who is with the Institute of Ecological Chemistry in Munich, Germany. Tom Wiese of the US Environmental Protection Agency, Research Triangle Park, NC, performed the endocrine disrupter screening tests on separated enantiomers. Bill Champion and coworkers of Chiral Technologies, Inc., Exton, PA, USA performed the preparative HPLC separation of the enantiomers of $o,p'$-DDT, $o,p'$-DDD, dichlorprop acid, dichlorprop methyl ester, and $o,p'$-methoxychlor.

Gas Chromatography and Supercritical Fluid Chromatography with Selective Detection in Pesticide Analysis

Pilar Bou Carrasco and Josep M. Bayona
IIQAB-CSIC, Barcelona, Spain

1 INTRODUCTION

The generic term “pesticide” includes a variety of chemical classes with completely different physical–chemical properties and applications (i.e. biocide, herbicide, nematicide, fungicide, etc.). In addition to process control, which can be fulfilled by many analytical techniques such as spectroscopic and electrochemical methods, there is also an analytical need for multiresidue analysis in a variety of matrices including environmental and food products. Analytical schemes include sample pretreatment (preconcentration, clean-up) followed by determination oriented to the chromatographic technique. GC using capillary columns and selective detection systems is the preferred analytical technique because of its high resolution, speed of analysis, low cost and easy coupling to highly sensitive and selective detectors. However, due to the large variety of compounds with different physical–chemical properties, this analytical technique cannot be applied to all the pesticide classes. Other chromatographic and related techniques such as liquid chromatography (LC), SFC and capillary electrophoresis (CE) are needed for some specific classes of pesticides. In this article, the application of GC (section 2) and SFC (section 3) to pesticide determination will be covered but no other important analytical aspects dealing with sample preparation for pesticide analysis. Since most of the analytical demands of pesticide analysis include degradation products, the relevant ones are also considered. Furthermore, the high toxicity at very low concentration levels demands analytical techniques and, particularly, injection and detection systems compatible with trace analysis. Some integrated approaches combining in-line sample preparation to chromatographic determination, developed to improve the sensitivity of pesticide determinations, are also included. Finally, due to the complexity of matrices containing pesticides, only selective detection systems will be considered.

2 GAS CHROMATOGRAPHY OF PESTICIDES

As mentioned earlier, capillary GC combined with selective detection systems is widely used in pesticide determination. However, pesticide thermal lability is an aspect to be considered carefully. In fact, some chemical classes of pesticides, such as N-methylcarbamates (NMCs) and most ureas, are susceptible to degradation at the usual injection temperatures (250–310°C) used in conventional vaporizing injectors. To avoid this problem, the thermal labile analytes can be either derivatized (alkylation, esterification, etc.) or injected cold.
on-column or in a programmable temperature vaporizer (PTV) injector which allows injection at low temperatures or minimization of the residence time at high injector temperatures. However, for extremely heat-sensitive analytes, despite the fact that the injection can be carried out at low temperatures, they can be thermally degraded in the column during the chromatographic run. Therefore, the derivatization step is unavoidable for those analytes if GC determination is envisaged. Generation of volatile derivatives allows the elution of pesticides at lower temperatures, avoiding their thermal degradation during the chromatographic run and also minimizing the adsorption on the active sites of the capillary column. Despite its clear analytical benefits, derivatization introduces an additional step in the analytical scheme, increasing the analysis time and the chances of analytical errors (i.e., partial derivatization yields, formation of by-products, etc.). Therefore, alternative analytical techniques such as LC, SFC or CE are preferred for these specific analytes.

Nevertheless, derivatization reactions of pesticides are used in several laboratories and are summarized here for the most important pesticide classes.

**Phenylureas.** Derivatizations commonly used for some phenylurea determinations are alkylation with alkyl iodide and acylation with heptfluorobutyric acid (HFBA). Another option is their hydrolysis to obtain the corresponding amines, followed by derivatization to obtain the fluoroacyl derivatives since they are more stable and show higher response than their precursors.\(^2\)

**Sulfonylureas.** Sulfonylureas cannot be determined in their free forms by GC because of their thermolability. This can be overcome either by methylation with diazomethane in order to obtain the monomethyl or the dimethyl derivatives, or by derivatization with pentafluorobenzylbromide (PFBBr).

**Ureas and Carbamates.** Acetylation with acetic anhydride for determination of carbamate pesticides and some ureas is also reported.\(^2\) Another approach for the determination of NMCs is the hydrolysis using trimethylsulfonium hydroxide followed by derivatization with pentafluoropropionic anhydride.\(^3\)

**Phenoxyacids.** They need to be derivatized to obtain volatile compounds: esters or ethers. Alkyl, chloroalkyl, silyl or pentafluorobenzyl derivatives are obtained. Silyl derivatives do not provide enough sensitivity for trace level determination, whereas the methylesters are commonly used for residue analysis. However, these last derivatives of common phenoxyacids provide low retention times and present interferences. Typical derivatization reagents are diazomethane, boron trifluoride or the complex boron trichloride–methanol and PFBBr. The last derivatization increases the response in ECD but a sample clean-up prior to injection is required to avoid interferences.\(^2\)

### 2.1 Injection Techniques

#### 2.1.1 Vaporizing Injectors

Pesticide analysis requirements based on existing regulations in environmental and food products demand determinations at trace level. Therefore, the split injection is not suitable for the former mentioned instances, because the carrier-gas mixed together with the evaporated sample is vented and only a small fraction of the sample reaches the analytical column. Furthermore, it is not suitable for thermal labile compounds. The splitless injection technique is preferred because most of the evaporated sample injected is transferred to the column, increasing the sensitivity, but its volume is limited to a few microliters by the injector volume. Focusing methods of analytes must be used to obtain narrow peak bands. They are usually achieved by injecting the sample at lower column temperatures than the solvent boiling point which temporarily acts as a stationary phase.\(^4\)

Splitless injection is suitable for samples containing non-volatile by-products which are retained in the injector port.\(^5\) Hajslová et al.\(^6\) evaluated the matrix effects when determining pesticide residues in water. Figure 1 shows a chromatogram illustrating the effect of crude extract clean-up. In Figure 1(a) a narrower “pesticide fraction” is collected (from 16 mL instead of 15 mL when the first analyte λ-cyhalothrin appears in the eluate). Reduced recoveries are obtained for some analytes when collecting the narrower fraction. Nevertheless the analysis of real matrices justifies this election because many interfering coextractants are detected in the broader “pesticide fraction” as shown in Figure 1(b).

Splitless injection is also used in solventless injection techniques such as solid-phase microextraction (SPME).\(^7\) As in the conventional splitless injection with an organic solvent, the purge valve is closed before the injection and, in this case, activated when the thermal desorption period is completed (few minutes). In order to assure a suitable peak shape, column temperature should be kept low enough to obtain the band focusing effect.

One disadvantage of vaporizing injection when a wide range of pesticides is simultaneously analyzed is the so-called discrimination of the high boiling vs the volatile analytes. This effect can be minimized by optimizing the injection variables (i.e., hot needle, injection speed, boiling point of solvent, etc.) but not completely eliminated.\(^4\) Therefore, calibration should be carried out with the same analyte or, if not available, with a closely eluting
compound. In the following discussion, the major classes of pesticides that are GC amenable with conventional vaporizing injectors are reported.

The use of electronic pressure programming injectors, which increase the pressure of the column inlet immediately after the injection, reduces thermal degradation of analytes.\(^3\)

**Organochlorine.** Most organochlorine pesticides (OCPs) can be analyzed in conventional vaporizing injectors. However, at high injector temperatures (280 °C), thermal degradation of chlorinated diphenylethanes leads to the formation of dehydrochlorination products. These alkene-type products, namely dichlorodiphenylethlenes (DDEs), can occur in environmental samples since they are metabolites leading to biased results. Thus, injector temperature must be optimized to avoid this thermal degradation reaction during the GC analysis.

**Organophosphates.** These constitute a broad class of GC amenable pesticides. Only very few organophosphorus pesticides (i.e. CL 26691, pyraclofos and azamethiphos) among 68 examined have been identified as not being GC amenable.\(^1\)

**Pyrethroids and Triazines.** These can be determined in conventional vaporizing injectors. Only cypermethrin among the 32 pesticides belonging to the pyrethroid class has been identified as not being GC amenable in conventional GC vaporizing injectors.\(^1\) No single 1,3,5-triazine among 14 compounds examined has been identified as not being GC amenable.

### 2.1.2 Cold Injection Techniques

**Programmable Temperature Vaporizer.** Liquid samples are injected into a cool vaporizing chamber that is rapidly heated following the syringe needle being withdrawn.\(^4\) Discrimination of the high-boiling analytes is minimized when the sample is injected and its precision is much better than the conventional hot injection techniques.\(^4\) A PTV injector does not completely solve the thermal degradation of pesticides but is preferred to splitless injection for this particular analysis in terms of minimum discrimination and the larger injection volumes allowed without detector configuration modification.

**On-column Injection Techniques.** The sample is directly injected into the oven-thermostated column inlets.
or into an uncoated precolumn which is connected to the analytical column.\(^{14}\) The injector body is continuously cooled (primary cooling), as is the inlet of the precolumn during the injection and the post-injection time (5–20 s) (secondary cooling). In this way, not only the sample evaporation is avoided but also peak broadening. Furthermore, the evaporation process is highly reproducible. Whereas this technique is optimal to inject labile solutes, it is not convenient for highly polar analytes prone to adsorb on the active sites of the capillary wall surface. Many determinations of NMCs by using GC in the cold on-column injection have been carried out in order to reduce their thermal degradation.\(^{3}\)

Several extraction techniques have been coupled to GC by means of an on-column interface in order to improve the procedural detection limits. Jongenotter et al.\(^{8}\) described a gel permeation coupled to GC with FPD for organophosphate pesticides (OPPs) in olive oil with a flow-regulated on-column transfer of the gel permeation chromatography (GPC) fraction, controlled in a time basis. The temperature range is wider than in other methods, and allows the detection of a broad volatility range of OPPs (i.e. mevinphos, acephate and monocrotophos). Pocurull et al.\(^{9}\) describe a solid-phase extraction (SPE) coupled to gas chromatography/mass spectrometry (GC/MS) using an on-column interface to determine organophosphates, organochlorines, triazines and thiocarbamates in tap water.

### 2.1.3 Large Volume Injection

Injection devices have been developed to accommodate large sample volumes (up to several hundreds of microliters) into the capillary column in order to minimize tedious extract concentration steps prior to the analytical determination. Large volume injections (LVIs) can be carried out by using on-column injection, where the sample is slowly injected and the solvent is concurrently evaporated from the analytes in a retention gap (e.g. bare deactivated fused silica tubing). Solute focusing is achieved in the column inlet and the chromatographic separation begins when column temperature is ramped. A modified PTV injector also allows LVIs.\(^{10}\) Low volatility analytes are separated from the solvent in the injector port. PTV is preferred on an-column injector because the latter is suitable for dirty samples.\(^{5}\) Another possibility is using splitless injection for LVI. Analyte focusing is achieved by means of a precolumn with increasing film thickness with injection port distance coupled to a solvent venting valve where the analytical column is fitted.

**Applications.** Steen et al.\(^{11}\) obtained limits of detection (LODs) in the range from 5 ng L\(^{-1}\) for deethylatrazine to 0.2 ng L\(^{-1}\) for alachlor and metolachlor in a PTV LVI tandem mass spectrometric detector. The initial sample volume was only 200 mL of marine and estuarine waters and the injection volume was 40 µL after the sample pretreatment.

López et al.\(^{12}\) combined extraction procedures using low sample volumes (5–50 mL) with LVI/GC. A total of 16 organophosphates in clean water samples at the low concentration levels (nanogram per liter) were determined. The simplification in the extraction step by means of the LVI/GC technique allows less solvent consumption, produces less waste and reduces the analysis time. Suzuki et al.\(^{13}\) reported injections of 100 µL of extract from water samples, allowing pesticide determinations at concentrations of 0.1 µg L\(^{-1}\) with an enrichment factor of 20 in the splitless LVI. On the other hand, in the conventional splitless injection only a few microliters of sample can be injected. Thus, to determine pesticides at the former concentration, an enrichment factor of 500–1000 by liquid–liquid extraction (LLE) with dichloromethane is required.

### 2.2 Analytical Columns

Open tubular capillary columns of different length and diameter are used in the determination of pesticides (Table 1). Typically, 25–30 m length and 0.25 mm internal diameter (ID) are used in multi-residue analytical procedures where high efficiency is needed for the determination of a large number of pesticides. For some specific applications where a class of pesticides such as organochlorines (i.e. toxaphene) co-elute with complex mixtures of compounds (polychlorinated biphenyls, PCBs), longer columns are used (i.e. 50–60 m). The main disadvantage in the use of longer columns is their long analysis time. Recently, narrow bore (100–150 mm ID), shorter columns (5–10 m length) have been gaining acceptance because analysis time is significantly reduced without sacrificing resolution. The main limitation of narrow bore columns is their low sample capacity. The determination of mixtures of pesticides containing very few components can be accomplished in very short columns (1–2 m length × 0.25 mm ID) (Table 1) in a few minutes. Wide bore columns (0.53 mm ID) are also used in the determination of simple mixtures of pesticides because they offer a large sample capacity but due to their larger flow rate are not useful in most GC/MS applications.

### 2.3 Stationary Phases

Current pesticide determinations are accomplished by gas–liquid chromatography. Stationary phase selection is based on the polarity of pesticides. Furthermore,
enantioselective stationary phases are needed to separate quiral pesticides.

Another practical consideration in the stationary phase selection is the detector selectivity used in the pesticide determination. Ideally, the stationary phase composition should not contain any heteroatom detectable to minimize the column bleeding. For instance, halogenated stationary phases cannot be used in the ECD and cannot be used for cyanopropyl in the NPD because they give a strong baseline drift in temperature-programmed separation, thereby decreasing the detection limits. Finally, specialty columns are recommended in GC/MS applications since the outlet of the column is fitted to high vacuum in the ion source leading to an increased background at high programming temperatures which can contaminate the ion source.

2.3.1 Nonpolar

Typically, nonpolar stationary phases chemically bonded to a column surface are the most widely used in capillary GC because of their high efficiency and thermal stability (low bleeding and elevated maximum operational temperature) and long lifetime. These stationary phases contain 0–5% diphenyl and 0–95% dimethylpolysiloxanes (OV1, SE-54, DB-5, HP-5, etc.). More recently, silylarene-type stationary phases were introduced for GC/MS applications because they exhibited a lower bleeding rate compared to conventional polysiloxanes. These stationary phases are used in the determination of chlorinated and other lipophilic pesticides such as pyrethroids. Other applications of the nonpolar stationary phases are in the determination of derivatized polar pesticides such as NMCs or phenoxyacids (Table 1).
2.3.2 Medium Polarity

These stationary phases contain a higher degree (35–50%) of either phenyl and/or low substitution percentage (14%) of cyanopropyl polysiloxanes (OV-17, DB-35, DB-1701 or equivalents). They are used as secondary columns in the determination of OCPs. In addition, they are the stationary phase of choice for the determination of organophosphorus and triazines (Table 1).

2.3.3 High Polarity

Polar stationary phases contain a higher percentage of trifluoropropyl or cyanopropyl substituted polysiloxanes (DB-210, DB-200, DB-225 or equivalents). These stationary phases are useful for the determination of highly polar underivatized pesticides and herbicides (Table 1).

2.3.4 Chiral

Stationary phases used for chiral separations of pesticides are either derivatized or underivatized β- or γ-cyclodextrins which are usually chemically bonded to a typical polysiloxane (i.e. methyl, phenyl, or cyano substituted). Very few stationary phases contain the cyclodextrin directly bonded to the column surface. They have been used for the determination of chiral OCPs such as α-hexachlorocyclohexane, cis- and trans-chlordane, heptachlor, heptachlorepoxide, oxychlordane, 2,4'-dichlorodiphenyltrichloroethane (2,4'-DDT) and chlorinated camphenes (toxaphene congeners). Figure 2 shows the resolution of a racemic mixture of 2,4'-DDT enantiomers. In the case of polar pesticides such as the aryloxyalkanoic acids (i.e. dichlorprop and mecoprop), derivatization is necessary before the GC determination.\(^{15}\)

2.4 Detection Systems

Several properties, such as sensitivity, linear dynamic range, kind of response and its speed, noise, stability, etc., should be taken into consideration to select the convenient detector. Due to the fact that most of the pesticides contain heteroatoms, element-selective detectors are preferentially used in pesticide determination in real matrices. In Table 2, the properties of the main detectors used in the determination of pesticides are listed.

2.4.1 Nitrogen–Phosphorus Detector

This detector is widely employed in the determination of pesticides containing nitrogen or phosphorus because of its high sensitivity and selectivity towards these elements. The higher the molecular N:C ratio, the higher the sensitivity.

Thus, the detector has been applied to the determination of triazines, substituted ureas, thiocarbamates, dinitroanilines and chloroacetamides and concentrations in the parts per million to parts per billion range for residues of pesticides in soils, plants and waters.\(^{2}\)

Drapa\textit{e}r\(^{16}\) found a severe tailing in the organophosphorus pesticide analysis associated with the NPD mechanism being enhanced when the alkaline source ages. Tailing can be reduced or eliminated by recoating the source with rubidium and alumina powder. Response factors were increased 2- to 20-fold for phosphorus-containing pesticides by cleaning the bonded phase with an organic solvent, whereas the same factors for nitrogen-containing pesticides remain the same.

Organonitrogen. Sánchez-Brunete et al.\(^{17}\) reported LODs in the range of 0.001–0.02 µg g\(^{-1}\) for some chloroacetamides, thiocarbamates and triazines in soils. Garcia-Valcárcel et al.\(^{18}\) analyzed several dinitroanilines in air, plants and soils. LODs detected were at least 1 ng L\(^{-1}\), near 0.05 µg g\(^{-1}\) and 0.01 µg g\(^{-1}\), respectively. A total of 16 organonitrogen-containing carbamate pesticides, such as pirimicarb, bitertanol and aldicarb, were monitored among a group of 48 pesticide residues in 10 different agricultural commodities (e.g. potato, cabbage, and lettuce). Detection limits were 0.01 ppm. No peak interference was detected (except for the cabbage sample) and the only pesticide detected in the
unfortified samples (banana) was bitertanol. Triazines show the highest sensitivity in NPD. Low detection limits (0.4–4 ng L\(^{-1}\)) were reached for triazines in water samples. Triazines were detected in the 3–52 ng L\(^{-1}\) range. Residues of phenylureas such as chlorotoluron, isoproturon and metoxuron from soil samples were detected directly or after alkylation. Similar results were obtained for both methods and LODs were 0.01 µg g\(^{-1}\) dry wt for each herbicide. Several pyrethroids in plants were analyzed by NPD. No interference peaks were observed except for the apple and carrot samples. LODs were 0.01 ppm.

Organophosphates. LODs in the range of 0.003 µg g\(^{-1}\) (diazinon) and 0.01 µg g\(^{-1}\) (quinalphos) in vegetables are reported. For some matrices, such as alfalfa, broccoli and cauliflower, NPD is not a suitable detector method for organophosphates because it suffers from serious interference when crude extracts are analyzed, making it necessary to use a higher selective detector or to introduce a clean-up step in the analytical scheme.

2.4.2 Electron Capture Detector

This detector is highly sensitive towards compounds with electronegative atoms or functional groups, e.g. halogens, nitro, etc. Thus, it is very convenient to analyze halogenated pesticides or organohalogen derivatized pesticides in environmental samples (Table 2). The best response is obtained with polyhalogenated pesticides (i.e. hexachlorobenzene, lindane, DDTs) and some dinitroanilines. ECD is also used to detect phenoxyacids, benzonitriles, pyrethroids and substituted ureas. For trace level determination of pesticides, halogen atoms are

EI, electron impact (70 eV); NCI, negative chemical ionization; MS/MS, tandem mass spectrometry.
introduced in the pesticide molecule via derivatization (see section 1). In some particular “dirty” matrices, such as alfalfa, halogenated pesticides cannot be detected with ECD.\(^{(23)}\) This problem is usually overcome either with a clean-up of crude extract or with two-dimensional GC. Screening analysis of pesticide residues can be carried out reliably with the majority of foodstuffs with GC in parallel to ECD/NPD. Comparing cost–profit calculations of GC/ECD/NPD with GC/AED, the former is a cost effective choice to analyze pesticides in foodstuffs.\(^{(24)}\)

Some disadvantages of ECD are its narrow linearity range, limited selectivity and the detector maintenance due to the radioactive source. Linearity range and detector sensitivity have been improved by detector redesign\(^{(25)}\) such as Micro-ECD (HP 6890 series). In addition, nonradioactive ionization sources have been developed to replace conventional ECD, as in pulse discharge detection (PDD) which uses low energy ionization on helium doped with methane. Detection limits are in the femtogram or picogram range, depending on the analyte, and high detector temperatures can be reached with this detector (i.e. 400 °C).

### 2.4.3 Flame Photometric Detector

The elemental selectivity allows the determination of organophosphorus- and organosulfur-containing pesticides using appropriate bandpass filters. Quenching effects in the detection of organosulfur pesticides in matrices containing large concentrations of hydrocarbons and the nonlinear response for sulfur are the major drawbacks of this detector. Dual-FPD was introduced to solve this problem but the time-consuming optimization process has focused analytical interest towards pulsed flame photometric detection (PFPD) which improves the sensitivity in the determination of pesticides in complex matrices. Absolute detection limits of this detector are in the low picogram range for organophosphorus pesticides in the sulfur mode.\(^{(26)}\) Procedural detection limits in the range of 100 ppt for methylparathion from eggplants in the phosphorus mode have been reported.\(^{(27)}\)

### 2.4.4 Atomic Emission Detector

The multielemental detection capability of this detector makes it very powerful in the characterization of unknown compounds. In addition, detection limits of most common elements found in herbicides are in the picogram per second range (Table 2). Quantitative analysis of each element makes calculation of the approximate empirical formula of analytes feasible.\(^{(2)}\)

For some difficult matrices, such as leek, garlic, onion and cabbage, AED appears to be the optimal detection method for screening. The reliability of quantitative results at low concentration levels is remarkable.\(^{(24)}\) Lee and Wylie\(^{(23)}\) have found that AED has much better selectivity than NPD or ECD, and could be used to determine organochlorines, organofluorine and OPPs in agricultural matrices. Moreover, for some matrices it is possible to obviate several clean-up steps. Nevertheless, this detector is not very suitable if nitrogen is the only heteroatom present in the pesticide because the AED sensitivity and selectivity for nitrogen are lower than for other elements of interest.

### 2.4.5 Mass Spectrometry

The low cost of the electronic impact mass spectrometric detectors as well as the structural information provided in the full scan mode or the high sensitivity and selectivity in the selected ion monitoring mode, means that they replace other conventional detectors used in pesticide multiresidue analysis. Furthermore, mass spectral libraries contain over 120,000 compounds, which together with the powerful algorithms for analyte identification by library matching and co-eluted peak deconvolution make GC/MS the analytical technique of choice for the identification of unknown pesticides and their metabolites in real samples. All pesticide classes, provided that they are thermally stable (otherwise derivatives are needed), can be analyzed by GC/MS (see section 1). The combination of GC/MS with SPE allows the determination of a large number of pesticides at sub-microgram per liter levels in groundwaters by using the selected ion monitoring technique.\(^{(9,28)}\) In addition to a quantitation ion, at least one additional ion is used for confirmation purposes in the selected ion monitoring mode to assess the compound identity.

However, GC/MS in electron impact mode does not possess enough selectivity for the determination of pesticides from more difficult matrices. Two different approaches can be used to circumvent this limitation. One of them is negative chemical ionization using methane or ammonia as reagent gas. GC/MS in negative chemical ionization mode is very useful for the determination of pesticides containing electron-withdrawing groups such as organohalogenes, organophosphorus and the nitro-substituted aromatics because only these analytes are ionized. Usually, the molecular ion is the base peak of the mass spectra and the isotopic distribution gives additional information on the heteroatom content in the molecule.\(^{(29)}\) The molecular anion abundance strongly depends on the ability to stabilize it by charge delocalization of the radical formed in the electron capture reaction. In the case of organophosphates, the molecular anion is obtained only when the aromatic moiety is substituted with electron-withdrawing groups.\(^{(30)}\) Pyrethrin pesticides can be determined by a combination of negative chemical
ionization and positive chemical ionization.\textsuperscript{(31)} In fact, the preferred fragmentation modes involved cleavage around the ester oxygen single bond, with one fragment appearing in the positive and the other in the negative ionization mass spectrum. The main limitation of negative chemical ionization is the difficulty in reproducing mass spectral patterns because it depends on the type of instrumentation used and many other instrumental variables, such as ion source temperature and pressure, which make it difficult to build mass spectral libraries.\textsuperscript{(32)} Furthermore, the linearity range is narrower than for electron impact and the response factor strongly varies with the compound or even the isomer. Nevertheless, negative chemical ionization is useful in the identification of unknown compounds detected by ECD.

Another useful approach for the determination of pesticides in difficult matrices is the application of the MS/MS analyzer such as ion trap detector or triple stage quadrupole. The low cost of the ion trap detector and the possibility to perform \( n \) times MS/MS increased the interest of this instrumentation in the determination of pesticides because of the selectivity (Figure 3). In the literature, methods for the detection, quantification, and confirmation of more than 100 pesticides by GC/ion trap detection are available.\textsuperscript{(33)} Using MS/MS, very low detection limits (low parts per billion) and reliable confirmation (one precursor ion and two or more product ions) are simultaneously achieved.

2.4.6 Fourier Transform Infrared Spectrometry

This detection system gives additional structural information to GC/MS and GC/AED and is particularly useful for the identification of unknown degradation products of pesticides. Light-pipe was the first commercially available interface for GC/FTIR coupling. The main drawback of this interface was its limited sensitivity. This limitation has been overcome by the introduction of cryotrapping open split interfaces which allow detection limits in the picogram and subpicogram range by signal averaging.\textsuperscript{(34)}

2.5 On-line Techniques

Sample preparation techniques such as SPE or LLE techniques have been combined with GC, aiming to automate sample preparation steps. These techniques use LVI systems to introduce the organic extract obtained by elution of the SPE of the dried cartridge into the GC port. The main limitation of this approach is the large number of coextractants that are introduced into the analytical column. Heartcuts of LC in the normal phase, size-exclusion chromatography (as a clean-up) and reversed-phase\textsuperscript{(35)} mode have been coupled to GC using a multiport switching valve. The latter technique involves the direct injection of aqueous samples into the GC column, which can be troublesome. SPME is another approach used in sample preparation to avoid the use of solvents or the direct injection of water into the column. The extraction can be performed in the aqueous phase or in the headspace in equilibrium with the aqueous phase continuously stirred during the extraction.\textsuperscript{(36)} A variety of fibers have been used according to the polarity of the pesticide class.

2.6 Fast-speed Gas Chromatography

Very recently the increased demand for the determination of a large number of samples in food and environmental analysis has increased attention on the application of fast-speed determination of pesticides. Fast-speed GC can be accomplished with the use of short, narrow-bore columns (2–5 m length × 0.50–0.100 µm ID columns) leading to fast separations in minutes.\textsuperscript{(37)} The main limitation of this approach is the limited sample capacity of the column and its high back-pressure, which demands in most applications a modification of the GC port. A GC oven with very fast heating rates (up to 400°C) using inductive heating (so-called flash GC) has been recently introduced.

![Figure 3](image-url)
on the market. This technique allows the determination of simple mixtures of pesticides in only a few seconds.

3 SUPERCRITICAL FLUID CHROMATOGRAPHY OF PESTICIDES

Supercritical CO₂ is the most widely used fluid because of its relatively low critical constants and inertness. However, it can react in the presence of pesticides containing primary amine substituents that should be derivatized before SFC determination. Another limitation of CO₂ as a mobile phase is its low polarity but in the presence of polar analytes it is polarizable, which allows their solvation. An advantage of SFC in the determination of pesticides compared to GC is the use of lower temperatures, allowing the determination of thermal labile pesticides that are not GC amenable. In comparison to LC and capillary column supercritical fluid chromatography (cSFC), analysis time in packed column supercritical fluid chromatography (pSFC) is shorter. Four different mobile phase operational modes are currently used in SFC: (i) density programming; (ii) pressure programming; (iii) isobaric; and (iv) gradient programming using modified CO₂. Usually, density and pressure programming are applied in cSFC while isobaric or gradient programming is used in pSFC.

Until now, SFC has been applied to the determination of a large variety of pesticides and functional groups using different detection systems. Furthermore, it has been coupled to SPE for sample preparation. Although most of the SFC applications in the pesticide residue analysis have been focused on environmental matrices, several analytical schemes including SFC determination have been developed for pesticide determination in food matrices. Despite the potential advantages of SFC over more widely used chromatographic techniques, the high cost of SFC instrumentation precludes its widespread acceptance.

3.1 Packed Column Supercritical Fluid Chromatography

Most recent applications of SFC to pesticide determination use packed columns because of easier sample handling and because they allow LVIs without sophisticated hardware. Also, analysis time is much shorter than for cSFC or LC if a single column is used. The large flow rate used in pSFC allows its electronic regulation independent of pressure, which permits operation at optimum chromatographic conditions. Conventional LC columns are currently used in pSFC but polar modifiers must be added to supercritical CO₂ to elute polar pesticides. However, due to the small pressure drop along the column, pSFC offers the unique possibility to couple up to 10 analytical packed columns (5 µm particle size, 4.6 ID × 40 mm length) in series to increase the global efficiency, yielding high resolution of complex mixtures of pesticides. Several applications have been developed involving SFE/SFC coupling either to clean the sample or to increase the sensitivity of the detection system (see section 3.1.3).

3.1.1 Stationary Phases

The efficiency of different pSFCs for pesticide analysis has been evaluated for three different column packings (Si-60, 3 µm; C-18, 5 µm; and CN, 5 µm). The highest efficiency was obtained with the Si-60 column (45 790 N m⁻¹, 100 °C, 160 atm). It could be attributable to the smaller particle size of this packing. Stationary phases used in pSFC depend on the class of pesticides (Table 3). Consequently, further discussion will be organized according to pesticide chemical classes.

Carbamates. Different stationary phases have been evaluated for the determination of carbamates (i.e. cyanopropyl, hypersil, silica, diol). The most selective stationary phase for the 11 carbamates included in USEPA (United States Environmental Protection Agency) method 531.1 was a diol stationary phase using CO₂–methanol. Pressure, mobile phase composition and temperature are key variables affecting the analyte retention. A careful optimization of variables affecting the peak retention (i.e. pressure, temperature, modifier volume) is necessary since they control the retention time and reversal elution (change in the elution order) can be obtained if the pressure, temperature or mobile phase composition is slightly modified (Figure 4). The
SFC determination of carbamates is at least six times faster than the standard USEPA method 531.1 using LC involving post-column derivatization since the determination can be carried out without gradient programming and the chromatographic run is shorter, thus increasing the sample throughput.

Phenyl Urea and Sulfonylurea Herbicides. Phenylureas can be analyzed by pSFC. The best resolution was obtained with a diol column at low temperatures. At 60°C, thermal degradation was noticed. Sulfonylureas can also be analyzed with a diol column using methanol–CO₂ in a short analysis time (6 min) at 40°C and 200 bar (Figure 5). An increase of temperature led to a longer retention time due to a drop in the density of the mobile phase but no reversal in the elution of analytes was found.

Triazines. This was one of the first herbicide classes that was analyzed by SFC. Hypersil silica (5µm, 2.0 mm × 4.6 mm) is particularly effective for atrazines, allowing a baseline resolution of eight analytes in less than 30 min.

The retention behavior of OCPs (i.e. methoxychlor, DDT, DDE, aldrin and lindane) according to temperature on the reversed-phase C₁₈ showed no decrease of capacity factors (κ’) with temperature (60–130°C). Hexachlorocyclohexanes and 4,4'-dichlorodiphenyldichloroethane were analyzed with an octadecysilicilane silica column and eluted with neat CO₂ using an ECD determination. This analytical procedure was applied to SFE extracts recovered from carrots. Since most OCPs are thermally stable, GC/ECD is the preferred analytical technique because higher resolution can be obtained than in SFC/ECD (see section 2.4.2).

The separation of OPPs has been evaluated in different stationary phases (i.e. silica, NH₂, diol, CN, C-8, C-18 and PRP-1). An organic modifier of CO₂, such as methanol, was needed to improve the peak shape and...
to reduce the analysis time. The retention behavior of selected OPPs depended on the interactions between functionalities of analytes and stationary phase and decreased with analyte solvation (density increase). Cyanopropyl stationary phase was the optimum in terms of resolution and analysis time (15 min). This stationary phase was used for the determination of spiked OPPs from vegetable extract (i.e. cucumber, lettuce, and grapes).

The low pressure drop along the chromatographic column allows the possibility to use long packed columns providing high resolution in complex mixtures of pesticides. In this regard, nearly 100 thermal labile pesticides were analyzed with a 1.6-m-long column.⁴⁸

Some of the enantioselective stationary phases available for LC can be applied in pSFC for chiral separations of agrochemicals.⁴⁹ Although the resolution obtained in LC and pSFC is comparable, the latter can provide shorter analysis time as in other columns.

### 3.1.2 Detection Systems

pSFC uses LC-like detectors modified to the operational conditions of SFC because decompression is carried out following the detection. In this regard, pressure-resistant optical cells are mandatory in pSFC when spectroscopic detectors are used. Furthermore, GC-like detectors can be used but the large flow rates used in pSFC make splitting to other detectors necessary, allowing simultaneous multiple detection signals. Since modifiers are currently used in pSFC, detectors should be compatible with them. NPD, ECD, photoionization detection (PID) and sulfur chemiluminescence detection (SCD) have been used in the determination of pesticides. Applications of the different detectors according to pesticide classes are described hereafter.

**Carbamates.** The determination of carbamates has been carried out using NPD and ultraviolet (UV) detectors.⁴² However, the effluent of the analytical column must be split (1/1000) to allow the introduction of a few microliters of mobile phase for NPD or thermionic detection (TID). The signal ratio for UV/NPD detectors provides structural information that is useful for identity confirmation purposes.

**Sulfonylureas.** Sulfonylureas and their degradation products can be detected by ECD, NPD or UV.⁴³ Other pesticides with strong UV-absorbing chromophores (i.e. diflubenzuron, teflubenzuron, triflumuron) were readily detected at 254 nm in the UV region.⁴⁰

**Phenylureas.** Response surfaces of the ECD detector working at various detector conditions have been used to optimize the response using CO₂ modified with methanol.⁴¹ The ECD response of phenylureas is dependent on the amount of modifier but the LODs of phenylureas were in the low picogram level when 5% methanol in CO₂ was used as the mobile phase.

**Organophosphate and Organosulfur Pesticides.** A new generation of SCD systems was interfaced and tested for SFC with 100% CO₂ and CO₂ modified with methanol.⁴² The detection chemistry of SCD is based on ozone-induced chemiluminescence following a two-step combustion process of consecutive oxidation and reduction of sulfur-containing compounds. The LOD was 3 pg of sulfur (0.2 pg s⁻¹) and the molar response is independent of the analyte bonding environment.

A photoionization detector was coupled to an SFC apparatus to evaluate its performance.⁵³ Organophosphorus and organosulfur pesticides (i.e. disulfoton, ethion, and sulfoatep) could be detected at low nanogram levels using methanol-modified CO₂. In addition, TID has been used in the determination of OPPs in spiked vegetable samples allowing LODs in the low picogram level (50–165 pg), depending on the analyte.⁴⁷ This detector exhibited at least two orders of magnitude of dynamic range.

**Chloroatrazines.** A comparison between the thermospray LC/MS and electrospray SFC/MS interphase has been carried out in the determination of atrazine metabolites.⁵⁴ It was found that SFC/MS was the more sensitive for the less polar chloroatrazine compounds whereas the thermospray presented better sensitivity for the dealkylated products of atrazines.

### 3.1.3 In-line Supercritical Fluid Extraction/Solid-phase Extraction/Supercritical Fluid Chromatography

Two different approaches have been developed in order to improve the detection limits and sample throughput in pSFC, SPE and SFE for aqueous and solid matrices, respectively, were coupled to pSFC.⁵⁵ In-line SFE/SFC interfaces have been developed and utilized for trace analyses of OCPs and OPPs from complex matrices (i.e. chicken fat, ground beef, and lard).⁵⁶ A clean-up step, incorporating pSFC, allowed the fractionation of relatively small-sized, non-polar pesticides from the coextracted fatty materials. Clean extracts were analyzed by GC coupled to ECD and NPD.

Large volumes of aqueous samples (i.e. 100 mL) have been preconcentrated in-line in a precolumn (2.0 × 1.0 mm ID) or SPE disks and dried under a nitrogen flow at room temperature.⁴⁸ This approach allows very low detection limits (10 ppt) to be reached for pesticides and herbicides in aqueous samples. After drying, desorption with a supercritical fluid to the
analytical column was performed by switching restrictors mounted on valves. During desorption, analytes were focused on the top of the analytical column and the final determination was carried out by switching valves to transfer the extract to the analytical column.

3.2 Capillary Column Supercritical Fluid Chromatography

Most of the cSFC applications on the determination of pesticides published until the end of the last decade have used open-tubular small-diameter columns (typically 50–100µm ID). More recently the interest was focused on pSFC because of its easier operation, higher sample capacity and less instrumental constraints. In fact, the low flow rates used in cSFC demand the use of high-accuracy mobile phase delivery and flow control by fixed restrictors that do not allow its regulation independently of pressure or density programming. Therefore, the high theoretical efficiencies of the chromatographic column are partially lost during the density or pressure programming combined with the higher than optimum flow rates used in order to reduce the analysis time. Since multiresidue pesticide analysis demands high resolution, cSFC is not well suited for the determination of complex mixtures of pesticides analyzed in screening analysis. pSFC using multiple columns or packed microbore columns is more suitable for the determination of pesticides in real samples. Nevertheless, the easier interface of cSFC to GC-like detectors because of its low flow rates makes this chromatographic technique still attractive in the determination of selected classes of pesticides. In particular, packed capillary columns appear to be an area for development because analysis time, resolution and sample capacity are optimized.

3.2.1 Injection Systems

Theoretical considerations show that there are stringent requirements for the allowable injection volume in open-tubular cSFC. In this regard, injections lower than 96 nL should be performed in order to prevent no more than 1% loss of resolution in a typical column (10 m × 50 µm ID).(56) Typical injector hardware used in cSFC is a high-pressure valve equipped with a low-volume internal loop (hundreds of nanoliters). Nevertheless, this volume is still too high for most analytical columns and different injection systems have been developed to allow the injection of small sample volumes (dynamic split, delayed split and timed split). However, low sensitivities and relatively poor reproducibility are usually achieved in these split injectors and solvent venting systems have been developed in order to allow the injection of larger sample volumes such as solvent venting in a precolumn, or with gas purging and solvent backflush.(58–64)

3.2.2 Chromatographic Conditions

Analytical columns used in cSFC are narrow-bore open-tubular columns usually 25–100µm ID coated with bonded or highly cross-linked stationary phases to prevent the washout during the SFC programming conditions (Table 4). The most used stationary phase in the determination of pesticides is the substituted highly cross-linked polysiloxanes containing methyl or phenyl substituents because resolution is based on the high efficiency of the narrow-bore capillary columns. More polar stationary phases like cyanopropyl exhibited poorer coating efficiency because the low diameter of the

PESTICIDES

The column creates instability in the film distribution along the column. Despite this, polar stationary phases are useful because they provide a higher selectivity in comparison to nonpolar stationary phases.

Another important aspect is the column surface inertness. It must be minimized by deactivation to avoid the reversible or irreversible adsorption of polar pesticides which is particularly apparent at the low amounts of compound injected in cSFC. Table 4 reports some of the applications developed in pesticide determination using cSFC and the analytical conditions used. Density or pressure programming is used in most applications in order to increase the mobile phase solvating power, allowing the elution of a variety of pesticides. Alternatively, negative temperature gradient programming keeping isobaric conditions has been used for the elution of pyrethrins and pyrethroids.\(^\text{67}\)

Chlorinated Pesticides. These show a strong selectivity according to the chromatographic temperature since these analytes possess a remarkable vapor pressure. At high temperatures, chlorinated pesticide retention is mainly controlled by temperature, whereas at low temperatures fluid solubility is the more prevalent property affecting the retention of these analytes. A comparison between the effect of temperature in pSFC and cSFC shows that it is more relevant in the former columns.\(^\text{60}\)

Chromatographic reproducibility in terms of retention time, peak area and peak height has been studied in detail with respect to routine analysis of agricultural analytes. Typical reproducibilities using cSFC for herbicide standards at different concentrations (10–100 \(\mu\text{g mL}^{-1}\)) were 2–3% RSD (relative standard deviation) based on peak area and peak heights \((n = 5)\).\(^\text{60}\) Direct injection (without splitting) using a loop size of 1 mL gave a retention time reproducibility of 0.1% RSD.

3.2.3 Detection Systems

cSFC has great detector flexibility because of the low flow rates and in most applications neat CO\(_2\) is used as the mobile phase. Interfaces for cSFC coupling in ECD, TID, NPD, FPD, SCD, UV, MS, and FTIR have been developed.\(^\text{66}\)

UV absorbance detection has been applied to the detection of polar pesticides using modifiers to elute polar analytes that are difficult to elute from the analytical column by density programming. The photodiode array detector has been interfaced to cSFC for the sensitive determination of pesticides and herbicides.\(^\text{66}\) The sensitivity is similar to single channel UV but allows the deconvolution of overlapped chromatographic peaks and peak confirmation. The LODs of SFC/UV were compared to those of LC/UV for analyzing sulfonylurea herbicides.\(^\text{67}\) The sensitivity of both chromatographic systems was comparable due to the broad UV transparent window of CO\(_2\) in comparison to organic solvents.

NPD was applied to the determination of carbamates and other nitrogen-containing pesticides by using neat CO\(_2\) as the mobile phase. The method has been applied to standard mixtures and real samples reaching LODs below 1.6 ppb in complex matrices.\(^\text{68}\)

The flame photometric detector is element selective to sulfur, phosphorus or tin depending on the bandpass filter mounted between the flame and the photomultiplier. However, when CO\(_2\) is used as the mobile phase, signal quenching occurs because the luminescence of organosulfur compounds is at the same wavelength that CO\(_2\) absorbs. Therefore, the application of FPD has been restricted to organophosphorus and organotin compounds. An increased sensitivity in tin-selective FPD was obtained when large hydrogen flow rates were used, reaching detection limits in the low picogram range (Figure 6). Different detector

![Figure 6](https://example.com/figure6.png)

Figure 6 cSFC chromatograms of organotin chlorides obtained with tin-selective FPD at 50 °C. Injection was performed at 76 atm and then programmed to 250 atm at 3.5 atm min\(^{-1}\) after a 10-min isobaric period. Compound identification: 1, TPtTCI; 2, DBTCl; 3, TBTCl; 4, TeBTCl; 5, DPhTCl; 6, TPhTCl. (Reproduced from Dachs and Bayona\(^\text{70}\) by permission of Elsevier.)
configurations have been used for detection in single, dual and pulsed FPD. Selective and sensitive determination of labile sulfur-containing pesticides has been achieved by using SCD (see section 2.1.2). Its detection limit was 12 pg, it exhibited three orders of magnitude of linearity and the sulfur to carbon selectivity was $10^7$. The limited signal quenching allows the use of moderate amounts of polar modifiers, enabling the elution of polar sulfur-containing pesticides.

The selective determination of OCPs has been carried out using two different detectors (ECD and TID) in a nitrogen atmosphere. Detection limits of both detectors were strongly compound dependent and ranged from high femtogram to low picogram. The dynamic range of ECD is four orders of magnitude. The Fourier transform ion mobility detector response operated in the negative ion collection mode and a commercially available ECD detector were compared for organochlorine compounds. Pressure programming led to a baseline drift in the electron capture detector in contrast with the Fourier transform ion mobility detector that always exhibited a stable baseline.

Several classes of thermal labile pesticides such as carbamates or nonvolatile phenoxycacids have been successfully analyzed by cSFC/MS in the chemical ionization mode. Accordingly, different sensitivities and fragmentation patterns in mass spectra can be obtained depending on the reagent gas used. In this regard, when ammonia is used, less fragmentation was obtained, showing a base peak corresponding to $(M + 18)^+$ in comparison with methane which led to a base peak corresponding to the substituent cleavage.

cSFC/MS has been used in the determination of OCPs using a double focusing instrument and different ionization modes. Detection limits were in the low nanogram level independently of the ionization procedure (positive or negative ion) used. Positive-ion methane chemical ionization resulted in a relatively abundant $[M + H]^+$ ion, whereas positive ion isotubane and ammonia appeared not to be amenable to the detection of chlorinated pesticides. The electron impact charge exchange mass spectra of the pesticides did not match the library spectra. CO$_2$ was an efficient moderating gas giving relatively large amounts of $[M]^-$, in addition to some fragment ions.

Gas chromatography/mass spectrometry (GC/MS) is irreplaceable in pesticide analysis. Nowadays international bodies consider mass spectrometry (MS) the method of choice for pesticide analysis and quantitative methods using GC/MS are more and more numerous. The key characteristics of GC/MS in pesticide analysis are its selectivity and sensitivity, but other important features will be considered in detail in the specific sections on identification and quantitative analysis.

A great advantage of GC/MS in identification is that it gives a mass spectrum that can be easily and quickly compared on-line with a library of more than 200,000 mass spectra. Specific pesticide libraries are available with hundreds of compounds. Mass spectra can be obtained with just a few picograms of compound injected and gas chromatography (GC) can separate analytes. This is an unbeatable feature of GC/MS.

In quantitative analysis, sensitivity is often excellent and selectivity is better than with other GC detectors. Multiresidue analyses can easily be done. The use of internal standards labeled with stable isotopes allows an accuracy which is not achieved with common methods. These characteristics facilitate sample processing because cleanup stages are not necessary in many cases.

Major limitations in the use of GC/MS depend on GC limits. Thus, very polar and thermally labile pesticides, not suitable for GC analysis, cannot be analyzed by GC/MS. Other limitations are the cost of the apparatus and the relative complexity of the method, compared with the simpler GC detectors. However, these limitations are gradually becoming less important as GC/MS instruments become simpler and cheaper.

1 INTRODUCTION

Pesticides are ubiquitous pollutants and have effects on the environment and human beings even in minute amounts. Fortunately, this is not the case for all compounds, but this category has nevertheless been viewed with suspicion for years. Since the adverse
activity of pesticides may appear at low doses, analysts have been pushed to develop sensitive methods for analyzing them. However, the fact that there are hundreds of pesticides belonging to many different chemical classes complicates analysis. Furthermore, many more compounds originating from the parent pesticide may be present and cause adverse effects.

Selective detectors offer good sensitivity and enough specificity towards certain classes of pesticides. For instance, electron capture detection (ECD) is widely used for chlorinated and brominated pesticides, looking at chlorine or bromine. GC/MS can do the same but better. Thus GC/MS has been used to analyze chlorinated and brominated pesticides, looking at chlorine or bromine. GC/MS can detect these atoms without any possibility of error, because it measures both isotopes of these atoms, while ECD can detect a halogen “aspecifically”, but we cannot establish whether it is chlorine or bromine.

However, the real power of GC/MS goes much further. It can consider not only a specific atom, but also a molecule (as molecular ion) or a molecular (charged) fragment, characteristic of the pesticide. This further increases the specificity. Then, in addition, we can look at many of these characteristic ions for a single molecule, improving the specificity and obtaining a sort of fingerprint. As regards specificity, GC/MS is also superior to immunoassays, which tend to be affected more by interfering compounds (cross-reactivity). In fact, MS is employed in GC/MS, which separates the mixture of compounds present in a typical pesticide analysis from an environmental sample, a biota or a food matrix.

2 APPLICATION OF THE MAIN TECHNIQUES FOR PESTICIDE ANALYSIS IN GAS CHROMATOGRAPHY/MASS SPECTROMETRY

2.1 Electron Ionization

In EI (previously called electron impact), the analyte is introduced into the source, which is under vacuum, and bombarded with electrons, which break the molecules and give many charged species. For MS the positive ions are the most useful. A more detailed description of MS is given in the article Electron Ionization Mass Spectrometry. For the introduction of the analyte GC is employed in GC/MS, which separates the mixture of compounds present in a typical pesticide analysis from an environmental sample, a biota or a food matrix. Further details on GC/MS are given in the article Gas Chromatography/Mass Spectrometry. GC/MS offers a unique possibility to analyze halogenated pesticides. Chlorine and bromine in the molecule are easily detected by the appearance of ions as doublets, separated by two mass units. Chlorine presents two isotopes in nature, chlorine-35 and chlorine-37, in a definite ratio (about 3:1), while bromine has two isotopes, bromine-79 and bromine-81, almost equally abundant. As a result, ions containing one of these atoms show a typical doublet: see Figure 1 for an example of a pesticide with one chlorine. In this figure, the ion at m/z 215 is due to the molecule of atrazine bearing the isotope of chlorine-35, while at m/z 217 the sister ion, due to the molecule with chlorine-37, appears. Similarly, the ion at m/z 200 corresponds to the loss of one methyl group from the molecular ion at m/z 215; the ion at m/z 202 corresponds to the same loss from the ion at m/z 217. All ions with chlorine (molecular or fragment ions) present this behavior (they are split into two in a typical relative abundance), while ions not containing chlorine are singlets (plus the ion at one higher mass due to carbon-13, mainly). This helps in interpreting mass spectra.
If more than one of these atoms is present the situation is more complicated, but still manageable, e.g. see the mass spectrum of 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane (DDT) (Figure 2). The pattern of these ions is typical of molecules with five chlorine atoms and can be easily calculated with probabilistic algorithms. From inspection of the mass spectrum the analyst can understand whether and how many chlorines and bromines are present in the pesticide (and in the individual fragment ions).

2.2 Chemical Ionization

If a softer method is used to ionize the molecules, there is less fragmentation so the mass spectrum shows a more abundant molecular ion. In CI a gas is introduced into the source, such as methane, isobutane or ammonia. Both positive and negative ions can be used. More details are given in the article Chemical Ionization Mass Spectrometry: Theory and Applications.

Positive ion chemical ionization (PICI) is used less than negative ion chemical ionization (NICI). NICI offers high sensitivity mainly because there is less noise, because abundant negative ions occur only in special cases. The opposite happens with PICI: generally there is more noise because of the high abundance of ions produced in the source. In PICI, addition of protons and in some cases of protonated gas may happen. The molecules give ions with multiples in many cases, and pseudomolecular ions (at higher mass then expected). Nitrated compounds present MH\(^+\) ions. An example is given in Figure 3(a–c).

NICI is useful if the pesticide contains chlorine or bromine or aromatic nitro compounds. An example of the same compound under different ionization conditions is given in Figure 3(a–c). CI mass spectra are less reproducible than EI spectra. NICI may be valuable for identifying these compounds, for instance in the case of transformation products (TPs) when we know that the parent compound contains these atoms or residues (see section 3.2). Halogens can be intentionally introduced into the molecule using derivatization with fluorinated residues.

CI is used for identification for specific purposes and not as a regular tool, for several reasons. It is more likely to produce different mass spectra depending on the experimental conditions and instruments. For instance, the different gases used may produce different mass spectra and the pressure of the gas itself is important. CI is less common than EI and mass spectral libraries

![Figure 1 Mass spectrum of atrazine.](image1)

![Figure 2 Mass spectrum of DDT.](image2)

![Figure 3 The mass spectrum of octachlorobornane (component of toxaphene) in three different ionization modes [(a) EI, (b) CI and (c) NICI].](image3)
relate to EI. However, if we need confirmation of the molecular weight, PICI can be used or NICI will give useful mass spectra of halogenated pesticides, or very high sensitivities in quantitative analysis.

2.3 Tandem Mass Spectrometry

Tandem mass spectrometry (MS/MS) uses an ion to generate other ions as a result of fragmentation. To do this we need to separate the ion of interest from the others. Generally this is done in the MS analyzer; only the ion of interest is transmitted. Then at the exit of the first ion analyzer, the selected ion is dissociated with the help of a gas. In the case of the triple quadrupole, this is done within the second quadrupole. The selected ion produces a spectrum of ions (daughter ions), which are the ions it generates (see Figure 4a and b). This spectrum is typical of a given parent ion and informative on the structure of this ion. If a parent ion P gives a daughter ion D, the second spectrum may be highly specific and further increases the specificity of MS.

A different mass spectrometer, the ion trap, can separate the ions on a timescale, within the same physical space. Thus, by selecting appropriate potential values it is possible to allow only a specific ion to “survive” in the first phase and then to record its daughter ions in a second stage. This process can be repeated, obtaining MS\textsuperscript{n} capabilities.

MS/MS can be used for identification, to gain information on the structure of the ions. It can be used in quantitative analyses where it generally offers high sensitivity and selectivity. The selectivity comes from the typical dissociation involved in the transition from the parent ion P to the daughter ion D. The sensitivity is due to the low noise, which is typical in this case.

2.4 Derivatization

Derivatization is used in GC to produce volatile derivatives of compounds with little or no volatility. For instance, silylation is a typical procedure for derivatizing hydroxylated compounds. These may give mass spectra where the molecular ion is not present, because they undergo loss of water after EI. Hydroxylated molecules also present some problems in their chromatographic behavior, often resulting in tailing peaks with the commonly used GC column phases. Silylation, with \(N, O\)-bis(trimethylsilyl)trifluoroacetamide (BSTFA) for example, can be used to characterize hydroxylated compounds better and to obtain more clearly resolved GC peaks. After derivatization, the chromatographic peak of the hydroxylated compound will disappear and a new chromatographic peak will appear, corresponding to the derivatized compound. The mass spectrum of this new compound can be interpreted considering some common losses presented by silylated compounds, such as the loss of the methyl (15 u) or trimethylsilanol (90 u). Another example is trichlorfon. This compound is unstable in GC conditions, decomposing at the injector temperature. Special conditions, such as glass wool in the injector, enhance this degradation. However, if trichlorfon is derivatized with trifluoroacetic anhydride it remains stable in GC analysis and the limit of detection (LOD) is improved.

The most commonly used derivatizations for pesticides are summarized in Table 1. In the following sections we shall consider specific cases for the different pesticides.

2.5 Ion Analyzers

There is no single mass spectrum for a given compound. We shall not deal here with mass spectra obtained using interfaces which are not GC, such as liquid chromatography/mass spectrometry (LC/MS),

fast atom bombardment (FAB), capillary electrophoresis/mass spectrometry (CE/MS) and others, and shall confine ourselves to spectra obtained under GC/MS conditions. The mass spectra of pesticides obtained under CI conditions (positive and negative), described above, generally look different from the EI mass spectra (see Figure 3a–c). EI is by far the most widely used mode, but in this case too different mass spectra can be obtained. The electron voltage can be modified, in order to obtain more information on the fragments or on the molecular ion. Using different mass spectrometers the mass spectra present some differences, mainly in the relative abundances of the ions. Magnetic instruments were widely used in the past and mass spectra libraries are based on spectra recorded in the EI mode. Some mass magnetic instruments operate at high resolution. This means that they can distinguish masses which are very close, less than $10^{-4}$ u. For pesticide analysis, however, high resolution is not necessary in most cases, although it certainly improves the selectivity and gives cleaner ion chromatograms, with fewer interfering peaks. Consequently, better resolution may reduce the need to purify the sample. We referred to high resolution in relation to MS. High resolution is a term sometimes used also for GC, with capillary columns, but for GC high resolution is actually common so we shall not use this term in this context.

Quadrupole instruments contributed to the spread of MS because they are less expensive. They have some advantages, such as the absence of hysteresis, which allows faster scans and the possibility of recording ions in the same group using selected ion monitoring (SIM) regardless of the mass ratio. On the other hand, quadrupoles have lower resolution (high resolution is not possible), a more limited mass range (depending on the quadrupole) and the sensitivity may be lower. As we have seen, generally there is no need for high resolution for pesticide analyses. The mass range is usually enough and this is not a limiting factor, although some exceptions may appear with very particular quadrupole instruments operating at a very limited mass range. As regards sensitivity in quantitative analysis, in most cases quadrupole instruments reach enough sensitivity for common pesticide analysis.

Recently another mass spectrometer has appeared on the market, offering a good performance/price ratio: the ion trap. This instrument has been produced for several years now and has the advantage of offering MS/MS at low cost, as described above. The ion trap can record spectra of pesticides, injecting only a few picograms of analyte in several cases. Its high scanning sensitivity reduces the need to select specific ions for selective monitoring to reach enough sensitivity in quantitative analysis. A problem arising mainly in the first models was that the spectra showed behavior between those of EI and CI. Indeed, depending on the concentration of the analyte, the ion trap had a tendency to show reduced fragmentation. This affected quantitative analysis, on account of the different behavior of the analyte at different concentrations. Modern ion trap instruments give more reproducible results and quantitative analysis of pesticides is comparable to that with other mass spectrometers.
Time-of-flight instruments can be expected to catch on more in the future, but at the moment there are only limited applications for pesticide analysis and we shall not go into details.

3 IDENTIFICATION OF PESTICIDES AND RELATED PRODUCTS BY GAS CHROMATOGRAPHY/MASS SPECTROMETRY

3.1 Pesticides

GC/MS is unique in its ability to provide informative spectra of pesticides. The mass spectrum contains a kind of fingerprint specific to individual pesticides and can be used for automatic comparison with mass spectral libraries containing up to 200 000 spectra. Specific pesticide libraries are available. The computer compares the acquired mass spectrum with those in the library in seconds. The software suggests one or more spectra similar to the unknown spectrum. Generally, ions at higher masses are considered more significant, because they are more characteristic; at low masses many compounds have fragments. The software considers this feature of mass spectra.

The comparison is based on the presence of reference ions in the mass spectra of the unknown compound, but not vice versa. This makes the procedure more flexible towards impurities. In theory we might, for instance, have one extra ion in the mass spectrum of the unknown compound, suggesting impurities. If, however, we have an extra ion in the mass spectrum of the standard which is missing in the unknown mass spectrum, this should be considered with suspicion as it is indicative of a wrong identification.

The mass spectral library is a collection of spectra obtained in different laboratories and reported in the literature. The library may have more than one spectrum for the same compound. The library reports spectra obtained in the EI mode, as we said before, but not necessarily in GC/MS. EI can be obtained by introducing the analyte directly into the source [the direct inlet system (DIS)]. This gives a mass spectrum of a compound which is not suitable for GC analysis. For instance, if we analyze a sediment it may be common to find molecular sulfur. This gives a typical mass in which several ions are separated by 32 u. The library may suggest the spectrum of maneb. This is because maneb, once introduced into the ion source with the DIS, gives a decomposition mass spectrum dominated by sulfur ions, similar to that of molecular sulfur (see Figure 5a and b). The analyst must be aware of possible mistakes in identifying compounds on the basis only of the mass spectrum. The real identification requires confirmation with an authentic standard. This principle applies to all identification techniques, not only MS.

3.2 Transformation Products of Pesticides

It is not necessary to interpret the mass spectra when identifying pesticides using the library, which compares the occurrence and the abundance of the main ions (see below). However, interpretation of the mass spectrum is essential for identifying unknown pesticides and related compounds, such as degradation products, metabolites, transformation compounds and chemical impurities related to the synthesis of the pesticide. Mass spectra have been reported for many of these compounds and included in the libraries, but often they are not considered in as much detail as their precursors.

The literature provides many examples where GC/MS proved essential for the identification of pesticides and related compounds. Several studies refer to the characterization of a TP, this expression including metabolites, degradation products and adducts. In this case the analyst can take advantage of the specific knowledge available, stemming from the problem considered. For instance, in the case of the identification of a TP we know the parent compound and it is therefore important to study its mass spectrum. A TP is a related compound, and its structure can be expected to be similar or at least related to that of the parent compound, even though there may be hundreds of potential metabolites. A fragment ion in common in the mass spectrum of the TP and of the parent compound is a strong indication that that moiety has been maintained in the TP, so transformation affected another part of the molecule. Similarly, the loss of the same residue indicates that the group which is lost in
the two molecules, the parent compound and the TP, is unchanged.

If the molecule contains two or more atoms of chlorine or bromine, they can be easily detected in a TP. Of course, other information may be useful too, such as GC retention time of a TP compared to the parent compound. As an example, see Mangiapan et al.⁴

### 3.3 Impurities in Pesticides

Pesticides are produced, for their final use, as a technical grade product. This means they are often contaminated by impurities. For instance, when atrazine was found in many parts of northern Italy, it was often together with simazine and propazine. MS is a major tool for confirming the real identity of the impurities.

Even when analytical standards are used for laboratory experiments, pesticides come with impurities. This was the case for alachlor, which complicated the identification of TPs, since some of the compounds possible after degradation were already present in the original compound.⁴ Glyphosate was also contaminated by some impurities, determined by GC/MS.⁵

Particular impurities are nitrosamines, which occur in pesticides with amines, and are subject to special control on account of their possible carcinogenic effects. The common method is to use GC with a thermal energy analyzer (TEA), which is selective for NO and NO₂ residues; as an alternative, we used GC/MS looking at the ion at m/z 30, corresponding to NO, thus improving the selectivity of the method.⁶

A special situation may arise when derivatives are used. The derivatization compounds have been found to be contaminated with impurities, which may complicate identification of the derivatives.⁵

### 4 QUANTIFICATION OF PESTICIDES BY GAS CHROMATOGRAPHY/MASS SPECTROMETRY

#### 4.1 General Characteristics of the Method and Comparison with Other Methods

For quantification, GC/MS employs the ions specific to the pesticide of interest, as they appear in the mass spectrum. This is SIM or selected ion recording (SIR). The use of these ions gives MS a unique ability. The analyst should select the ions on the basis of their abundance, but this is not the only criterion. The ions at higher mass are more specific, while those at lower mass are shared with many compounds, and this increases the likelihood of interfering compounds. Furthermore, some ionic traces are “dirtier”, because there are often contributions from common compounds or from column bleeding. For instance, the ion at m/z 149 commonly contains peaks due to phthalates, which are ubiquitous contaminants, while the ions at m/z 207 and 281 and several others show high noise due to bleeding from silicone columns. On the other hand, GC/MS is insensitive to the other contaminants, which may complicate analysis for some specific GC detectors, such as ECD and NPD. For these selective detectors, the problems are more serious than contamination in GC/MS.

For quantitative analysis the selectivity is due to the retention time (as with the other selective detectors) and to the ion chromatograms, which is a more specific feature than the response to a flame ionization detection (FID), ECD or NPD. However, in many cases the selectivity is further improved, because a second ion is added for the quantitative analysis. When two ions are used, the likelihood of a compound interfering with both is very low. Furthermore, we have to consider the relative intensity of the two ions: if in the reference mass spectrum the two ions are in a given ratio, this ratio has to be confirmed in the sample, with 10–15% imprecision, for instance. This ratio is a fourth element of specificity, with the retention time and the specific responses to the two ion traces. Of course, we can add yet another ion trace to improve the selectivity.

What happens if we find that the ratio of the two ions is not correct? It means that there is an interfering peak, and we can easily establish on which of the two ion traces it appears. We can then consider the cleaner trace, and calculate the amount of the analyte; if this is below a given fixed amount, which should be checked, we can conclude that the concentration of the pesticide is in any case below the fixed limit. If our aim is to determine its concentration or if the limit is exceeded considering the less contaminated trace, we can probably choose a third trace, to be used for the analysis, which may not be contaminated by interfering peaks. In this sense, GC/MS is a flexible technique, and the method can be modified according to the sample to be analyzed.

MS/MS generally gives higher selectivity than GC/MS since it refers to a very specific ionic transition. If we consider two ion traces, as is common in the case of quantitative analysis with GC/MS, one of the two traces may have impurities, but with MS/MS to see the signal both the ions must be involved, the parent and the daughter ion, and they must be linked by a particular transition, which means less likelihood of interfering peaks and a cleaner background, and thus a higher signal-to-noise (S/N) ratio.

In several cases the complete mass spectrum of the pesticide has been recorded with the ion trap instrument and used for quantitative analysis; this procedure couples quantitative and qualitative analysis, which in all the other cases are split in GC/MS, and is thus particularly

interesting. Further studies are still needed to explore the potential of this approach.

4.2 Detection Limits and Ranges

The LOD differs for different compounds. This is because each analyte gives fragmentations in different ways and yields. This may complicate quantitative analysis, because it requires standard and calibration curves obtained with the authentic compound. This should in any case be the procedure followed with all detectors. In the case of unknown compounds, semiquantitative analysis is less accurate in GC/MS than with other detectors. In quantitative analysis of pesticides, the LOD with GC/MS is adequate in most cases, once the best procedure is adopted. For instance, for pesticides in water the LOD was good enough for 50 compounds even applying the strict European Union (EU) limit of 0.1 ppb. ECD may offer better sensitivity in some cases, but generally this is not required, and very good sensitivities are achieved with GC/MS using NICI for the compounds which give good sensitivity with ECD.

Table 2 shows some indicative (not exhaustive) examples of LOD. With GC/MS some of the LODs are achieved without any purification, which is commonly required for other detectors. In GC/MS the ranges are often excellent, allowing a wide selection of theoretical analysis. There may be some limitations, which apply not only to GC/MS, however, but also to GC in general or to more specific cases. For instance, memory effects are possible with solid-phase microextraction (SPME), and this must always be checked, not only with SPME.

Ion trap instruments, especially the old ones, may show saturation of the source, which induces a sort of chemical autoionization. In the worst cases this produces a different mass spectrum for the analyte, depending on the concentration, with a consequent loss of linearity in the curve at higher concentrations. Modern instruments take this into consideration.

4.3 Isotope Dilution Mass Spectrometry

GC/MS offers a unique opportunity to improve the accuracy of measurement. The analyst may add a standard with isotopic labeling to the sample before any processing step. This compound is almost identical from the physicochemical point of view with the analyte of interest. The only difference is that it contains some atoms labeled with the corresponding non-natural isotope. Carbon-13 or deuterium is commonly used. MS distinguishes the labeled compound from the natural compound on the basis of the mass of the ion. We can easily keep account of the actual recovery of the analyte of interest or of loss due to evaporation or degradation. This procedure is particularly useful in the case of labile pesticides.

The number of labeled atoms to be introduced into the molecule varies. The rule is that one should check the mass spectrum of the analyte, looking carefully for the abundance of the satellite ions that commonly occur at higher masses. This is because some carbon-13 and deuterium are also present in nature. In the case of chlorinated or brominated compounds the situation is worse, because there is a high abundance of chlorine-37 or bromine-81. As a consequence, a shift of at least three or four mass units is required.

Several labeled pesticides are commercially available. Their price may be high and this limits their use. An alternative is to prepare the necessary standard. For deuterium labeling this may be simple because deuterium exchanges easily in several cases. However, care is needed when using these deuterated standards, since the labeling may be lost under particular conditions, such as altered pH.

5 APPLICATION TO DIFFERENT MATRICES

The specificity of pesticide action has led to the development of specific analytical methods for the various matrices. These methods are important from a toxicological point of view, to monitor food for sale and protect human health from dangerous residues of pesticides in the diet. National legislations establish different admissible residue levels for each pesticide in each commodity, and the analyst must take account of these specifications.

The GC/MS approach with its high specificity is particularly useful for analyzing pesticides in several matrices. This technique is now widely used not only for confirmation of residues, but also as a primary quantitation method. The wide applicability of GC/MS instruments for solving problems in the analyses of complex matrices is illustrated in this section.

5.1 Environmental Matrices

5.1.1 Water Samples

Most GC/MS applications for pesticide determination relate to the analysis of environmental and drinking waters. There are different reasons. First, the regulations on water quality are severe in several countries as regards maximum allowable concentrations of pesticides: the EU sets a limit of 0.1 µg L⁻¹ for individual pesticides and related products and 0.5 µg L⁻¹ for total pesticides.

Standard analytical protocols for water monitoring have been widely developed in the USA. The United States Environmental Protection Agency (USEPA) is responsible, and this agency has introduced GC/MS-based protocols during the past few years. The standard
Method 525 is an example: the sample is prepared with a solid phase extraction (SPE) cartridge or an Empore disk containing octadecylsilica as solid-phase; after elution with dichloromethane, the extract can be analyzed by GC/MS with LOD in the range 0.08–0.14 µg L⁻¹ in water for some triazines and acetanilide herbicides.

The SPE approach for water sample preparation for these analyses is particularly favorable: the liquid sample is passed through a column containing a solid phase, analytes are adsorbed and concentrated on this phase and subsequently eluted from the column with an appropriate organic solvent. Typical sample volumes in SPE are from a few milliliters to 10 L, depending on the column size and the sensitivity required. SPE is rapid and reduces the use of toxic and expensive solvent; furthermore, the formation of possible emulsions in the liquid–liquid extraction (LLE) procedure is avoided.

Much research work has been done on SPE, as described later, and the development of specific SPE procedures by the USEPA is a clear indication of the success of this approach. Most of the other USEPA methods for pesticide residues in water are based on LLE procedures. This sample preparation is still frequently used in laboratories, also in GC/MS based methods, in view of its good reproducibility and simplicity. For example, LLE is employed in important official methods from the UK Standing Committee of Analysis (SCA): 1 L of water is extracted with 100 mL of hexane (in the case of pyrethroid insecticides) or diethyl ether after acidification of the water (for chlorinated phenoxy acids). These procedures comprise some successive cleanup steps, such as purification on a Florisil column (for pyrethroids) or hydrolysis of the extract (for phenoxy acids). GC/MS analysis is used in these UK methods only for confirmation of analyte identity using the NICI mode, after the usual determination by gas chromatography/electron capture detection (GC/ECD) and derivatization, in the case of chlorinated phenoxy acids. These procedures offer better sensitivity than the USEPA methods because of the use of a highly specific technique such as gas chromatography/negative ion chemical ionization mass spectrometry (GC/NICIMS).

Procedures based on LLE for water samples have been developed to analyze organochlorine, triazine and organotin pesticides by GC/MS. LLE methods are now being progressively replaced by SPE, as this modern sample preparation technique is gaining in popularity. The use of specific solid sorbents for extraction has been extensively reviewed and different SPE applications together with GC/MS have been developed (Table 3).

Most SPE applications are off-line procedures: the solid-phase column is eluted with a solvent, and a fraction

OPPs, organophosphorus pesticides; PCP, pentachlorophenol.
of this extract is injected with a microsyringe, manually or automatically. Solid phase extraction/gas chromatography/mass spectrometry (SPE/GC/MS) methods have also been developed with the extraction column coupled on-line to the GC system; extraction and analysis of the water samples for pesticide analysis are done on the same apparatus. Generally, the elution solvent is injected on-column, interfacing a retention gap between the injector port and the analytical GC column. This means that most of the organic solvent injected (typically 100 µL) is purged from the system through a solvent vapor exit, inserted between this gap and the column. The instruments can automatically dry the SPE column before the solvent elution step, using a purge gas line.

On-line SPE/GC/MS methods are sometimes called liquid chromatography/gas chromatography/mass spectrometry (LC/GC/MS) procedures. These methods have been used to detect triazines at low parts per trillion (nanograms per liter) levels; a short polymer-packed liquid chromatography (LC) precolumn is used as the SPE column. Typical extracted water volumes in LC/GC/MS are a few milliliters.

Another attractive recent sample preparation technique for water samples is SPME: a 1-cm silica capillary coated externally with a thin layer of a sorbent phase (a viscous polydimethylsiloxane or a crystalline polymer such as polycrylate (PA)), is immersed in the liquid sample under stirring; analytes partition in this capillary and in the sample to reach an equilibrium. After the desired extraction time, the fiber is withdrawn from the sample and the extract is directly injected into the gas chromatograph by thermal desorption, exposing the fiber inside a GC injector port.

The large number of methods with SPME coupled with GC that have appeared in recent years shows that this technique can be a valid alternative to SPE and LLE. Ground, tap and river waters, effluents from sewage plants and leachates from landfills have been extracted with SPME, and GC/MS was performed without any purification step.

Most SPME methods for pesticide analysis used a polar polymeric fiber phase (PA), on account of the mid-polarity of most analytes. LOD are in the low nanograms (µg/L) level, but with relatively low precision (15–23% standard deviation in the quantitation), using SIM.

Corn herbicides in soil were determined using GC/MS, but only as confirmation besides gas chromatography/nitrogen–phosphorus detection (GC/NPD). Samples were extracted with ethyl acetate and analyzed without any purification step; GC/MS was sufficiently specific and the LOD in the SIM mode was more than 10 times lower than that with full-scan operation.

GC/MS was also used as confirmation for the analysis of some thermally labile phenylurea herbicides; an ion trap GC/MS system was applied to elucidate the structures of the thermal decomposition products formed in the GC injector and selected for quantitation in the direct GC analysis of these herbicides. Each phenylurea gave a characteristic phenylisocyanate from thermal decomposition, and ion fragments from each of these products were selected for confirmation by GC/MS down to the 0.01 mg kg⁻¹ level, in the SIM mode. The SIM mode was also used to confirm some sulfonylurea herbicides in soil using membrane disk SPE. In membrane SPE the phase is settled on the surface of a Teflon™ filtering disk; compared with the SPE cartridges, the extraction process here is faster since higher water fluxes can be achieved in the disk than with an extraction column.
Klaffenbach and Holland \( \textsuperscript{23} \) extracted soil samples with 0.1 M sodium hydrogencarbonate buffer; analytes were separated from this solution with membrane disk octadecylsilica SPE. After solvent elution of the disk and derivatization with diazomethane, GC/MS operating at resolution 1000 was used to analyze the \( N,N' \)-dimethyl derivatives of these herbicides in the eluate.

GC/NICIMS has been considered recently for the determination of toxaphene in soils.\( \textsuperscript{46,59} \) This organochlorine pesticide is a mixture of about 700 polychlorinated bornane congeners; it is difficult to analyze because of this complex composition, and highly selective methods are needed. In view of the presence of chlorine atoms in the analytes the NICI mode of MS was used, and selectivity was increased using a magnetic sector instrument operating at resolution 10,000; these operating conditions were effective in the analysis of soil samples containing interfering compounds such as polychlorinated biphenyl (PCB) compounds.\( \textsuperscript{59} \)

GC/NICIMS in the SIM mode was also used to analyze some pyrethroid insecticides in soil and sediments.\( \textsuperscript{36} \) Samples were extracted with a mixture of hexane and dichloromethane in an ultrasonic bath and extracts were cleaned up with Florisil chromatography. The NICI mode of MS was chosen because all the selected insecticides contain halogen atoms (chlorine or bromine). The authors reported a limit of quantification for this method in the range 0.012–4.4 \( \mu \)g kg\(^{-1} \).

The reported NICI mass spectrum of deltamethrin presents some peculiarity: the most intense peaks are due to the bromine anions at \( m/z \) 79 and 81. A similar NICI mass spectrum was observed for another halogenated insecticide, DDT, but of course in this case chlorine was detected.\( \textsuperscript{60} \)

Organotin compound are widely used as pesticides and antifouling agents. A GC/MS method has been recently developed to monitor their accumulation in sediments with accelerated solvent extraction (ASE).\( \textsuperscript{45} \) ASE is a new sample preparation technique: solid samples are extracted with a pressurized fluid held at 50–100°C. Volatile solvents can be used at high temperatures because of the pressurization, so less solvent is required and extraction times are shorter than with traditional methods. Organotin compounds have been extracted with a methanolic mixture of sodium acetate and acetic acid. GC/MS detection allowed the use of deuteriated analogs to achieve high precision (relative standard deviations <5%) and low LOD (0.4–2 ng g\(^{-1} \), starting with 2.5 g of sediment).\( \textsuperscript{45} \)

Durand et al. compared the performances of GC/MS at two resolving powers (1000 and 10,000) and that of gas chromatography/tandem mass spectrometry (GC/MS/MS) in the determination of chlorotriazine pesticides in soil;\( \textsuperscript{61} \) the MS/MS technique (on a hybrid magnetic quadrupole instrument) achieved higher specificity in the analysis of real soil samples than the other two single MS procedures.

Some preliminary experiments indicate that SPME methods can be applied for the analysis of pesticide residues in soils using GC/MS.\( \textsuperscript{43} \)

### 5.1.3 Air

GC/MS has been applied by different research groups in the field of air monitoring. The common procedures for sample collection are for adsorption: air is forced through a tube containing a specific solid medium, using a sampling pump. In some cases, filter sheets made of glass or quartz fibers are placed before the adsorption column to collect analytes present in the air particulate. Different solid media are used: Amberlite\textsuperscript{\textregistered} XAD-2,\( \textsuperscript{63,64} \) silica gel,\( \textsuperscript{62} \) Tenax\textsuperscript{\textregt} TA\( \textsuperscript{65,66} \) and a polyurethane foam (PUF) plug.\( \textsuperscript{67} \) High volumes of air (100 L to 1000 m\(^3\)) are sampled with these materials, in view of the low concentrations of the pesticides (1–40 pg m\(^{-3}\) for DDT in continental air).\( \textsuperscript{62} \)

The trapped pesticides are desorbed by solvent extraction or thermal desorption; in this latter case, a thermostable material (Tenax\textsuperscript{\textregt} TA) is used as adsorption medium so the sampling tube can be heated directly connected to the GC/MS system.

### 5.1.4 Biota

GC/MS has been successfully applied in the analysis of very complex matrices such as animal tissues. The NICI mode has been employed to analyze different organochlorine pesticides in mouse and rat brain and mouse plasma;\( \textsuperscript{68,69} \) these methods were highly selective, permitting direct analysis of the sample extracts without any purification. Identification of some lindane metabolites in the rat brain was possible using NICI in the full-scan MS mode.\( \textsuperscript{68} \) The fragmentation was limited in the NICI spectra of endosulfan reported by these authors and the spectrum was dominated by the molecular ion signal; in another study,\( \textsuperscript{69} \) however, the target endosulfan ions chosen for SIM in NICI were the chlorine ion signals (\( m/z \) 35 and 37). This is an example of how NICI conditions influence the spectra; ionization depends on several experimental factors (such as ion source temperature and geometry, reagent gas and pressure).

Different pesticides were detected in pine and spruce needles with GC/MS techniques: PCP was analyzed at low parts per billion levels after derivatization with diazomethane to give the corresponding methyl ether.\( \textsuperscript{8} \) Other organochlorines such as hexachlorocyclohexane (HCH), hexachlorobenzene (HCB), DDT and metabolites has been found in conifer needles using GC/MS in the
EI(70) and NICI(3) modes. The EI procedure employed a Florisil chromatography purification step and isotopically labeled internal standards in the quantitation. As an alternative, the NICI method avoided the chromatographic cleanup step using a concentrated sulfuric acid treatment on the vegetable extract, and employed a brominated analog of DDT as an internal standard.

An example of the use of the technique to monitor organochlorine bioaccumulation in aquatic organisms is provided by Galceran and Santos:(71) homogenized and dried samples of different mussel species were Soxhlet extracted with hexane–dichloromethane (1:1), and the extract was cleaned as described elsewhere.(70) GC/MS in the SIM mode was used for confirmation of results obtained first with ECD.

Development of analytical procedures for toxaphene in biological samples is complicated by its complex nature (as mentioned in the soil section) and by the numerous interferences from other chlorinated compounds. A procedure was developed for toxaphene analysis in fish samples:(72) after extraction with dichloromethane, three successive chromatographic cleanup steps are used to separate first the analytes from the lipids [with gel permeation chromatography (GPC)] and then from the other chlorinated contaminants (with Florisil and silica gel chromatography). GC/MS was used in the SIM mode with EI positive ion detection, with an LOD of 1 µg kg⁻¹. Compared with this method, the NICI procedure developed for these same matrices was less time-consuming, since only GPC and silica gel purifications were needed,(73) demonstrating the higher selectivity of the NICI technique. The NICI spectrum of toxaphene is characterized by limited ion fragmentation with respect to PICI and EI (see Figure 3); the presence of these high-intensity NICI ion signals explains the higher sensitivity of this technique compared with PICI and EI methods. In particular, the same authors(73) found that the NICI mode was approximately 100 times more sensitive than EI or PICI for the analysis of toxaphene. The minimum detectable amount of toxaphene with this method was 75 pg.

5.2 Food Samples

GC applications to pesticide residue analysis in foods are as numerous as those to water, and the number of GC/MS methods has grown continuously since the 1980s. GC/MS has been considered as a secondary confirmation technique in multiresidue methods for samples exceeding the maximum residue level (MRL), (74) but its use as a primary screening tool is becoming frequent.(75)

Advantages over the classical element-sensitive detectors convinced the Food and Drug Administration (FDA) to use GC with ion trap MS in their multiresidue analytical protocol based on the Luke extraction method.(76) This instrument was compared with the other detectors for the determination of over 100 residues in real contaminated food samples. The FDA concluded that GC/MS was able to provide a determination and confirmation simultaneously in samples using the full-scan mode down to the sub-parts per million level, but probably an additional cleanup step was necessary to obtain acceptable quantification for all the target compounds and better sensitivity.

Sample preparation in most of the GC/MS procedures is based on the traditional solvent extraction (see Table 4 for a tentative list and section 6). In addition to the official extraction methods (Luke and Mills methods),(89,90) specific procedures have been considered.

Solventless procedures such as SFE and SPME are other extraction methods considered for foods analysis using GC/MS. SFE methods have gained ground in the last decade.(73) Sample preparation can be highly selective for pesticide extraction, and the extracts can be injected directly into the instrument without any purification step. The possibility of dramatically reducing the use of toxic solvents is another advantage that encouraged food analysts to consider this technique. SFE and GC/MS have been used together in the development of a multiresidue method for 46 pesticides in fruits and vegetables:(91) CO₂ was used as a supercritical fluid, and extracts collected using an octadecylsila solid trap directly connected to the extraction chamber. Analytes were recovered from this trap with acetonitrile elution. No quantitative recoveries were achieved for all the pesticides with this method (values ranged from 0% to 114%, depending on the analyte), meaning this supercritical fluid extraction/gas chromatography/mass spectrometry (SFE/GC/MS) approach needs some improvement before its application in regulatory laboratories.

Unlike the previous method, SFE using CO₂ modified with methanol was effective in the analysis of fluazifop-P-butyl in onions, with GC coupled with quadrupole MS; (92) it is common practice to add a polar solvent to the supercritical fluid in SFE methods in order to increase the solvent strength and the diffusion of the fluid into the sample matrix.

Applications of SPME in food analysis have been reported for wines;(43,93) with these methods, the SPME fiber is directly immersed in the liquid sample, without any pretreatment. Quantitations were based on a calibration curve obtained with pesticide-spiked wine samples(93) or with a standard addition method,(43) and LOD in wines for 14 most frequently used pesticides were in the 0.1–5.5 µg L⁻¹ range. (93) Orange juice was also analyzed with this SPME/GC/MS approach.(56)

Validation of immunoanalytical methods for pesticide analysis is an important task in the development of such...

procedures. GC/MS is generally accepted as the leading technique for comparison in most types of enzyme-linked immunosorbent assay (ELISA).94–96 Recently, two commercial ELISA kits for procyomidone residue analysis in wines were compared with an SPME/GC/MS method.97

5.3 Other Matrices

Some specific matrices such as solid wastes and animal feed preparations have been analyzed for pesticides using GC/MS methodologies. Official GC/MS methods to evaluate the content of different organochlorine pesticides (DDT, toxaphene) in solid wastes have been developed by the USEPA, namely Methods 8250 and 8270.98,99 A GC/MS procedure has been reported for the determination of the organotin acaricide cyhexatin (tricyclohexyltin hydroxide) in animal feed samples;16 a derivatization step with a Grignard reagent (ethylmagnesium bromide) is used to give the alkyl derivative of this pesticide, allowing GC analysis. Tricyclopentyltin hydroxide is used as an internal standard.

6 APPLICATIONS FOR DIFFERENT PESTICIDE CLASSES

6.1 Introduction

We shall consider here the major pesticide classes individually, indicating the peculiarities of the major pesticides. This section reports applications and examples related to the previous ones. Since some examples have already been presented, mainly in section 5, we shall not repeat them here.

The most frequently used methods for analyzing pesticide contamination in the environment rely on GC separation and detection with various selective detectors. The choice of detection technique depends on the
chemical characteristics of the target analytes and on the required specificity and sensitivity.

### 6.2 Multiclass Methods

Maximizing the number and types of analytes to be determined with given resources is considered the most practical and economical approach in a monitoring program. One of the main aims of recent analytical procedures is to monitor the overall content of pesticide contamination, often involving different chemical classes and different applications in environmental matrices.

GC/MS can monitor a wide series of different pesticides, regardless of their chemical class, in a single analysis (see Figure 6 for an example). In order to achieve the low legal limits set for pesticide contamination, extraction and enrichment steps are necessary before GC/MS analysis.

The preconcentration step can be carried out by different extraction techniques, such as solvent extraction, including solid–liquid extraction (SLE) and LLE, used in several USEPA methods, SPE, SPME and the more recent SFE.

Solvent extraction has been the main extraction procedure for a long time. Depending on the solvent’s characteristics (volatility, dissolving ability and miscibility with other solvents), different pesticides chemical classes can be extracted from food and environmental matrices. For multiresidue analysis of pesticides in fruits and vegetables, acetone partition/extraction and ethyl acetate extraction have mainly been used.\(^ {75,89}\) Organochlorine, organophosphate and organonitrogen pesticides are extracted well from food, feed and fat samples using an acetone–water mixture, or from fruit and vegetables using acetonitrile. SPE can be applied for multiresidue extraction procedures on a large number of pesticides belonging to different chemical classes.\(^ {41,100}\) Since various analytes with different chemical properties have to be extracted and analyzed in a multiresidue procedure, solid-phase columns or disks are chosen on the basis of their affinity toward the targets. Different extraction materials may be used simultaneously, in order to achieve exhaustive recoveries.

C\(_{18}\), phenyl and NH\(_2\) silica-bonded phase performances have been evaluated in the multiresidue/multiclass extraction of 50 different chemical pesticides from water samples.\(^ {41}\) The C\(_{18}\) phase was suitable for pesticides of medium polarity, whereas the most polar ones were extracted better with the NH\(_2\) phase. To shorten

![Figure 6](https://example.com/figure6.png)

**Figure 6** Total ion chromatogram of a mixture of 50 pesticides. (Reprinted from E. Benfenati, P. Tremolada, L. Chiappetta, R. Frassanito, G. Bassi, N. Di Toro, R. Fanelli, G. Stella, *Chemosphere*, 21, 1417 (1990), with permission from Elsevier Science.)
the sample preparation time and to achieve consistent recoveries, these different phases can be used simultaneously on the same column, so analytes can be extracted in a single preparation step.

Other materials have been tested for multiresidue pesticide extraction from water, including XAD-2 and XAD-7 resins. The XAD method can extract a wide variety of pesticides, including triazine, phenylurea, acetamide and aniline herbicides, carbamates and organophosphates and the simultaneous use of both resins achieves good recoveries.

SFE is another useful technique for the extraction of pesticide residues from food and environmental matrices. It has been successfully employed with the GC/MS procedure in the analyses of pesticides in vegetables. GC/MS procedures for multiresidue/multi-class screening of fresh fruit and vegetables have been developed for 143 selected compounds, several pesticides, some of their metabolites and other chemicals of concern in the safety of domestic or imported food. Including organophosphorus, organohalogen, organonitrogen, carbamate, triazine, thiourea and phenolic compounds and aromatic hydrocarbons and not considering chemicals not suitable for GC analysis, it has been demonstrated that the GC/MS procedure is powerful and one of the major analytical tools in multiresidue screening because it permits rapid routine and confirmatory monitoring of hundred of chemicals of food safety concern.

SPME/GC/MS procedures have been used in multiclass analyses; organochlorine, atrazine and thiocarbamate pesticides in environmental aqueous samples can be identified and quantitated using a polar fiber (PA, 85 µm) and employing GC/MS in both the scan and SIM modes. Good linearity and satisfactory LOD can be achieved, demonstrating the suitability of the newly developed extraction technique and the effectiveness of GC/MS for multiresidue pesticides analyses.

This technique can also be applied for pesticide extraction from food and environmental samples. Employing the appropriate fiber for the target analytes and limiting the interferences that complex matrices can generate, multiclass pesticide analysis can be performed after optimization of the experimental parameters. Both MS and MS/MS can be used for pesticides. Using the SPME procedure in a preparation step, samples for high-sensitivity studies can be obtained in a short time, achieving good specificity and low LOD.

Further improvements can be achieved in the evaluation of GC/MS data using macro programs which automatically run all the necessary steps for manual data evaluation. These programs take less time than manual data processing and the quality of evaluation can be maintained constant throughout the analysis. The use of a macro program in combination with a selected library containing a limited number of target compounds gives reliable results which the analyst can verify quickly.

6.3 Organochlorine Pesticides

Different environmental matrices have been extracted in order to quantitate organochlorine pesticides and several analytical methods have been developed. Here, we describe some of them.

The official USEPA method for the analysis of organochlorinated pesticides in water is Method 508, in which these compounds are monitored by GC/ECD, after LLE. ECD is mainly used in this kind of analyses, on account of its high sensitivity, but the need for confirmatory studies makes a GC/MS procedure more suitable for organochlorine pesticides.

Several GC/MS methods have been developed to analyze these chemicals not only in water samples but also in other environmental and food matrices. A Soxhlet apparatus is usually employed for extraction. SFE with CO₂ has been compared with the classical method for sediment analyses; furthermore, low LOD have been obtained with coupled SFE/GC/MS, making this a useful method for organochlorine pesticides in sediments.

Ultrasonic extraction has also been studied for analyzing DDT, 1,1-dichloro-2,2-bis(4-chlorophenyl) ethylene (DDE) and 1,1-dichloro-2,2-bis(4-chlorophenyl) ethane (DDD) in soil, with a view to saving time and minimizing the use of hazardous solvents in comparison with the classical Soxhlet extraction procedure. GC/MS indicated that ultrasonic extraction is suitable for the preparation of soil samples in organochlorine analysis. In addition, the lower temperature required may reduce the thermal degradation of DDT to DDE that can occur during Soxhlet extraction.

In organochlorine pesticide analyses it is better to use an internal standard for the standardization of the extraction procedure and subsequent instrumental determination. 13C-labeled HCB has been employed in quantification of unlabeled organochlorine pesticides in vegetable samples using MS in the NICI mode. A brominated compound, 1,1-bis(4-chlorophenyl)-2-bromoethane has been used as an internal standard in organochlorine pesticide determination in vegetable samples, with ECD and NICI mode MS detection.

6.4 Organophosphorus Pesticides

Organophosphorus pesticides (OPPs) can be analyzed by different methods although the commonest involves GC or LC. In many studies, GC with phosphorus flame photometric detection (FPD-P) has been the technique of choice because of its high selectivity, sensitivity and reproducibility. However, interference may occur when FPD-P is used in the phosphorus mode and sulfur is
present, or when thermally labile OPPs are present or when the liquid phase bleeds. To avoid mistakes, GC/MS can be used as a confirmatory technique. After some pretreatment steps, depending on the nature of the matrix to be analyzed (e.g., maceration and addition of drying agent for food samples and just solvent partition for water samples), LLE or SPE with various sorbents can be used to isolate them.\textsuperscript{15,29,107} LiChrolut EN and C\textsubscript{18} cartridges are suitable for the extraction of OPPs and the recently developed SFE can be considered a useful alternative in some cases.\textsuperscript{5}

These simple extraction procedures are suitable for the determination of OPPs at the nanogram level and there are few interferences. To achieve picogram-level determination, high-performance GC has been employed, using two columns with different polarity coatings, with a column switching technique.\textsuperscript{108} To avoid sample loss during the cleanup procedure and to correct the deviation of injection volume and the variability in detector response, internal calibration is often useful, particularly when labile or volatile OPPs have to be analyzed. Generally, different OPPs not involved in the analysis\textsuperscript{29} or deuterated analogs of the targets\textsuperscript{5} can be chosen for this purpose.

Different MS application modes have been tested. EI in the scan mode gives the most information about the compounds but it suffers from limited detection sensitivity; in the SIM mode the sensitivity is higher, but it is susceptible to interference. CI of OPPs generates base peaks with high mass in the positive mode (PICI), frequently the quasi-molecular ion, and in the negative mode (NICI) it gives mostly group-specific fragments of high intensity.\textsuperscript{108} In general OPPs, determination was more sensitive with NICI than with PICI or EI. Reliability, however, was better in PICI thanks to the abundant quasi-molecular ion. Pulsed positive–negative ion chemical ionization (PPNICI) was indicated as a good compromise with regard to sensitivity and reliability.\textsuperscript{108,109}

### 6.5 Herbicides

LLE is widely used for herbicide extraction from environmental solid samples, such as soils and particulates suspended in environmental waters. Depending on the chemical characteristics of the target analytes and on the type of matrix, different solvents have been used.\textsuperscript{30} To enhance recovery, ultrasonic extraction can be performed and, if herbicides with different acidity are present in the same sample, a double-space extraction procedure can be performed, using extraction solvents with different acidity.\textsuperscript{31,110}

SPE is also suitable for herbicide extraction from water samples. Different solid phases have been tested. For instance, styrene–divinylbenzene copolymer is suitable for a wide range of compounds\textsuperscript{110} and RP-C\textsubscript{18} cartridges are used for phenoxyalkanoic acid and other acidic herbicides.\textsuperscript{31} SPME procedures too are suitable for herbicide extraction and, since they are simple and can be automated easily, are ideal for in-field water measurements.\textsuperscript{11}

When target analytes are not suitable for GC/MS determination because of their chemical characteristics, a derivatization procedure has to be employed. As illustrated above, it is generally applied for non-volatile, unstable compounds or when there is the possibility of undesired reactions between the analytes and the stationary phase of the GC column. Many derivatization procedures have been developed to convert herbicides not suitable for GC/MS analyses into easier to handle chemicals. Acid herbicides can be converted to benzy1 esters by reaction with pentafluorobenzyl bromide or benzyl bromide;\textsuperscript{10,31} phosphorus-containing herbicides can be derivatized by reaction with N-methyl-N-(tert-butylidimethylsilyl)trifluoroacetamide;\textsuperscript{18} urea herbicides can be converted by pyrolytic methylation with trimethylsilylhydroxide or trimethylsulfonium hydroxide\textsuperscript{20} and sulfonyleurea herbicides can be converted into thermostable derivatives by reaction with diazomethane in ethyl acetate.\textsuperscript{32}

When selective detectors are chosen as a primary screening tool for herbicide determination, MS detection is a good confirmatory technique.\textsuperscript{30,111} However, considering the low contamination levels in environmental matrices, GC/MS is one of the main techniques for identification and quantification.

Often, an ion trap detector is chosen for trace determination because of its sensitivity. It identifies the contaminants on the basis of their total spectrum\textsuperscript{18,32} and fragmentation patterns of the compounds of interest can be studied at ultratrace levels. When co-extracted substances interfere, ion trap MS is used in the SIM mode, reaching high levels of confidence for identification in environmental matrices.\textsuperscript{10,31,33}

GC/MS analyses of water samples can be speeded up by introducing the aqueous sample directly into the instruments, without any extraction or preparation steps. GC/MS systems equipped with a silanized-glass reverse-cup liner and the splitless injection mode can be employed for direct injection analyses of water samples.\textsuperscript{33} Isotope dilution GC/MS is now widely used in herbicide analyses because it gives better accuracy and precision, and high-isotopic-purity, stable labeled standards are available.\textsuperscript{34}

### 6.6 Pyrethroids

Pyrethrin and pyrethroid pesticides are non-polar and non-systemic in plants, and their extraction is simple compared with the organophosphate or carbamate pesticides.
The solvent and the method used depend on the nature of the sample. Basically, the samples are homogenized with a single nonpolar solvent, such as benzene or hexane, or with a binary solvent mixture, such as hexane–acetone, hexane–2-propanol or light petroleum–diethyl ether. The pyrethroids are co-extracted together with a wide variety of lipophilic compounds during this process. If too many compounds interfere with the final determination, the sample can be cleaned up through liquid–liquid partition or column chromatography. The cleanup procedure is also influenced by the final determination. If the detection is selective enough, the cleanup procedure need not be so rigorous, otherwise more efficient cleanup is needed.

Samples with low water content, such as tea, tobacco and straw, are usually homogenized with a binary solvent mixture such as acetone–hexane (1:1) or hexane–2-propanol (3:1) or a single polar solvent, such as methanol, acetone or acetonitrile. Vegetables and fruits are usually homogenized with a binary mixture such as acetone–hexane (1:1 or 1:4) or hexane–2-propanol (3:1) in the presence of granular anhydrous sodium sulfate. Soil samples, after mixing and removing stones and vegetation, are extracted with acetone–hexane, methanol, acetone and acetonitrile by shaking or end-over-end tumbling for many hours.112

The clean-up procedure consists of liquid–liquid partition and column chromatography. The solvent partition systems used for pyrethroid residue analyses include acetone–hexane, acetone–dichloromethane, acetone–light petroleum, acetonitrile–hexane, methanol–toluene and acetonitrile–light petroleum.112

SPE can be used in place of liquid–liquid partition methods for the extraction of pyrethroids from matrices. Octyl (C8), ethyl (C2) and cyclohexyl (CH) sorbents are superior to the others in strength and selective elution. Adsorption chromatography is often used as an additional cleanup step to eliminate interference from co-extractives. Commonly used sorbents include Fluorisil, silica gel and alumina. These adsorbents are polar, thus retaining the lipid fraction on elution with organic solvents of low polarity. They are suitable for cleaning up apolar analytes such as pyrethrins, pyrethroids and organochlorine pesticides.112

GPC can be applied to cleanup procedures for environmental matrices in pyrethroid analyses.112,113

Generally, GC/ECD is the technique of choice for pyrethroid residues since most of these compounds contain halogen. For nonhalogen-containing pyrethroids, it is recommended to form halogenated derivatives before GC/ECD determination.112

However, MS, operating in the scan mode, serves as a structure-selective detection technique and permits the characterization and identification of TPs formed under special environmental conditions.114 High detection sensitivities have been achieved in the SIM mode at the parts per billion level.36 Ion trap GC/MS/MS is another means of determining the concentration and structures of pyrethroid insecticides. The characteristic ester cleavage of these compounds combined with selected ejection chemical ionization (SECI) and collisionally activated dissociation (CAD) procedure speeds up the analysis of protonated pyrethroids.115 In the SECI mode, specific ions from the CI gas are isolated before they are allowed to react with the neutral analyte molecules. This avoids EI by-products created during the ionization of the CI gas and the eluting analytes from being present in the final spectrum. The CAD procedure provides the ability to isolate specific ions after an EI event or CI reaction time, to excite them resonantly or nonresonantly and to detect the resulting product ions, providing more specific fragmentation patterns. Furthermore, the low cost of ion trap mass spectrometers makes them affordable for the structural characterization of complex mixtures.

6.7 Carbamates and Related Pesticides

Generally, LC techniques are preferred for the analyses of carbamate insecticides, but these methods require additional postcolumn derivatization steps to achieve the necessary detection limits and, except in LC/MS experiments, confirmatory MS analyses are necessary. Most of the carbamates now in use are not stable under standard GC conditions using a capillary column and hot splitless injection. They decompose in the hot injector forming phenols and isocyanates. The carbamates must therefore be derivatized. Various procedures have been optimized for single residues and for the whole group of N-methylcarbamates, to convert them to derivatives more suitable for GC/MS analysis. A rapid derivatization procedure involves conversion to phenol acetates by reaction with acetic anhydride.21 Since phenol acetates containing no heteroatoms are not suitable for ECD or NPD, these derivatives need MS determination. Working in the SIM mode, the GC/MS analysis of phenol acetates shows that high sensitivity can be achieved, making the procedure suitable for trace analyses of carbamates. The GC/MS technique has been successfully employed for the determination of metal–dialkyldithiocarbamate complexes in water. The EI technique has been tested for qualitative and quantitative analyses. On the basis of the mass spectra, the fragmentation patterns of the complexes have been studied.116

6.8 Fungicides

Fungicide residues have been studied in many matrices such as soil, plants, wine and water, by extraction with an organic solvent of low to medium polarity or by SPE. Different sorbents have been tested for fungicide
residue extraction. Good recoveries have been obtained using octadecylsilanes\(^ {35}\) and the newer porous carbon sorbents CARB GR, which offer thermal stability, chemical resistance and stability over a wide range of pH.\(^ {117}\)

GC/MS experiments have been carried out for confirmation of previous GC with selective detection analyses and as a primary screening tool, giving low detection limits.\(^ {35}\)

Fungicide residues have also been monitored using GC/MS/MS, providing confirmation of pesticides with a high degree of certainty and little sample preparation.\(^ {87}\)

### 6.9 Fumigants

Methyl bromide is one of the most widely used chemicals in fumigation. Its residues have been determined indirectly as total inorganic bromide. Various methods are available for its direct determination in different environmental matrices in field conditions.

The detection of methyl bromide in air is important at three levels: control readings for warning fumigation workers, workplace measurements and the measurement of methyl bromide in the atmosphere. Pellizari et al. developed a GC/MS method for air samples in which, after two adsorption steps on charcoal, the analyte is vaporized onto a GC glass capillary column, followed by MS to achieve detection limits at the nanograms per cubic meter level.\(^ {118}\)

For methyl bromide in water samples, headspace and purge-and-trap sampling methods have been generally used prior to its GC/MS determination.\(^ {119–121}\) Using an isotope-labeled internal standard, methyl bromide has been detected at the milligrams per liter level in water samples.\(^ {122}\) With methanol or polyethylene glycol extraction before GC/MS analyses of soil samples, as suggested in two different USEPA methods, detection limits of 1 mg g\(^ {-1}\) have been achieved.\(^ {120,123}\)

GC/MS determination of methyl bromide has been also performed with fish and post-mortem tissues. For fish samples, homogenization and purge-and-trap sampling methods have been coupled with GC/MS, reaching detection limits at the milligrams per kilogram level;\(^ {124}\) for post-mortem tissues, generally GC/ECD procedures have been used and MS detection has been employed as a confirmatory technique.\(^ {125}\)

### 6.10 Organotin Compounds

Generally, GC/MS analysis of tributyltin (TBT) is preceded by derivatization procedures. TBT can be converted to butyltin hydrides\(^ {126,127}\) or tetraalkyl compounds by Grignard reactions.\(^ {12–15}\) The Grignard derivatives are less volatile than organotin hydrides and are thermally more stable, thus facilitating MS analysis. In estuarine waters, after solvent extraction and derivatization with hexylmagnesium bromide, the tetraalkyl derivatives have been quantified with gas chromatography/flame photometric detection (GC/FPD), performing GC/MS experiments as confirmatory analyses. CI was chosen rather than EI because of the better sensitivity and because the formation of high-mass, high-intensity ions is ideal for SIM analyses of these compounds. Internal calibration was used to monitor nanograms per liter levels in environmental and laboratory samples.\(^ {15}\)

Tricloclohexyltin hydroxide (cyhexatin) is an acaricide effective against mites, used in a wide range of vegetables. It has been analyzed in animal feed samples using GC/MS (SIM) in the EI mode. Converting the analyte to the alkylated derivative and using a tricyclopentyl analog as an internal standard, LOD and quantitation at the nanograms per gram level have been achieved, showing more specificity than the other conventional detection techniques.\(^ {16}\)

### 7 CONCLUSIONS

GC/MS is now an established method for pesticide analysis and is versatile, sensitive, selective and accurate. Many different methods can be developed. GC/MS is used to confirm quantitative analyses with other detectors. However, with minimal effort laboratories could fully apply the powerful capabilities of GC/MS making a single GC/MS quantitative analysis, which is more robust, avoiding the need for confirmation after a first analysis with a less selective detector. GC/MS is an excellent technique for the identification of pesticides and related compounds and for their quantification. The approaches for these two different analyses are different and generally GC/MS is not as fast as other GC methods. Furthermore, its cost is higher. However, these factors are becoming less important as new, easier and cheaper instruments come on to the market, allowing the wider use of the technique.

Herbicides are generally synthetic organic compounds used to control unwanted vegetation or weeds. Application may either be directly to plants or soil to control unwanted terrestrial vegetation, or to water bodies to control aquatic weeds. Herbicide use plays an integral role in most crop production systems and agricultural production accounts for their greatest use. However, significant amounts of herbicides are also used in the forestry industry and to maintain pipeline, power-line and highway rights-of-way. Significant use also occurs within the urban setting to control weeds in lawns and gardens, and to maintain parks and golf courses.

Following application, a herbicide can undergo microbial or chemical degradation in soil, metabolism/conjugation in plants, and photodegradation by sunlight. It is
also well established that not all of the herbicide or its metabolites/degradation products remain within the area to which the herbicide was applied (Figure 1). Atmospheric transport mechanisms include droplet and vapor drift during application, post-application volatility losses, and wind erosion of treated soil. Transport in water occurs with snow melt, rainfall or irrigation runoff from treated land and via leaching and preferential flow of herbicides under both dry land and irrigated agriculture. Finally, herbicides and their metabolite/degradation products may also be removed from treated areas as residues in edible portions of crops.

Such transport can contaminate the air, surface and groundwaters and wildlife habitat leading to human and wildlife exposure and decreased environmental quality through wildlife habitat degradation and decreased biodiversity. Public interest in human safety and environmental quality with respect to pesticide use, as well as the requirement for the agrochemical industry to provide toxicology, soil persistence and crop residue data to support the registration of pesticides, have contributed to the driving force for development of sensitive MRMs. Such methods may be used to quantify residues of more than 100 pesticides and their metabolites/degradation products in a wide variety of matrices including soils, air, surface and groundwaters, plant tissues, human and animal tissues and body fluids.

Although several classes of pesticides can be analyzed in many matrices with these methods, this article will address only the determination of herbicides, and exclusively in biota; that is, terrestrial and aquatic animals and plants. While it is acknowledged that body fluids (urine, saliva, blood, milk) and environmental matrices (soil, air and water) are important matrices in toxicology/human health studies and environmental fate studies, respectively, analysis of these matrices will not be discussed.

The intent of this article is to review current extraction, derivatization, clean-up and detection methods for analysis of herbicide residues in plant and animal tissues, as well as highlighting emerging technologies. Since herbicides are targeted for uptake by plants, in contrast to animals which are only indirectly exposed, the majority of information regarding the determination of herbicide residues in biota derives from plants and discussion within the article will be weighted accordingly. Discussion will include considerations for the type of matrix, sampling, known or unknown analytes, acidic or base-neutral herbicides, metabolites/conjugates, and the level of sensitivity and degree of confirmation required.

Throughout the article, herbicides will be referred to by their common names as adopted by the British Crop Protection Council. Acidic herbicides are occasionally formulated as the free acid, but more commonly either as an alkali metal salt, an amine salt or as an ester. Unless reference is made to a specific salt or ester, acidic herbicides will be referred to by the common names for the parent acids.

2 GENERAL STRATEGIES

2.1 Quality Assurance/Quality Control

Sampling and analysis plans are defined by the hypotheses to be tested and the level of confidence required in drawing conclusions about the hypotheses. The statements about the level of confidence are called the data quality objectives. The quality assurance/quality control (QA/QC) program ensures that the study objectives are
met in an efficient and cost-effective manner. Quality control (QC) refers to the technical activities, such as the use of blanks, controls, and fortified blanks, and evaluation of the condition and integrity of analytical standards and stored samples which are used to control and assess the quality of the analytical data being produced. Quality assurance (QA) is the management strategy that ensures that the QC system is working properly. The strategy involves defining the QC activities necessary to meet the objectives, assessing the QC results to ensure that the system is in control, and reporting the QC data along with the analytical results so that the overall quality of the results can be assessed. The overall purpose of the QA/QC program is to provide analytical data of a known level of reliability that is acceptable to the end user as defined by the study objectives. The importance of QA activities in chemical analyses, in general, and pesticide analyses, in particular, has been reviewed.

An important QC activity in herbicide residue analysis is the control of inadvertent contamination of samples. To prevent cross-contamination between samples, it is essential that equipment and glassware, used for field sampling, subsampling and laboratory analyses, have undetectable levels of herbicide and metabolite/degradation product residues. Glassware is generally washed with hot softened water containing detergent, rinsed several times with hot water followed by several rinses with distilled/deionized water. In situations where very low residues are expected, a further rinse with an organic solvent such as acetone or hexane is recommended. Detergents should be chosen that do not introduce possible interfering compounds to the tissue extracts. Glassware used for pesticide residue analysis should be kept segregated from other glassware during the washing process. To minimize herbicide residue losses due to sorption during analysis, all surfaces wetted by the tissue extracts should be constructed of glass, stainless steel or Teflon®.

### 2.2 Type of Matrix

The most basic division of sample types is plant versus animal. Analytical methods can be very different for plants and animals because of differences in tissue, expected levels of contaminants, and the nature of metabolites and degradation products.

It is the edible portions of plants and animals that are most frequently sampled for herbicide residue analysis. Plant parts, such as fruiting bodies or kernels, leaves, stems, and roots are often subsampled and analyzed separately. With animals, study objectives may require that muscle tissue be sampled or fatty tissues and the liver in which persistent residues are most likely to accumulate. The choice of extraction and clean-up will be affected by the moisture level of the sample, the level of oils or fat, and the presence of co-extracted compounds and conjugates specific to plant or animal tissues. The concerns and approaches to the extraction and clean-up of plant and animal tissues are discussed in subsequent sections.

### 2.3 Type of Herbicide

Although there are exceptions, such as paraquat and diquat, herbicides fall into two basic chemical classes: base-neutral and acidic herbicides. Acidic herbicides, which comprise a relatively large group and account for approximately one third of currently used herbicides, include benzoic, oxyphenoxyalkanoic, phenoxyalkanoic, pyridinecarboxylic, quinolinecarboxylic, and substituted alkanoic acids, phenols and some miscellaneous acidic herbicides. Salts or esters of acidic herbicides usually undergo hydrolysis in the environment, or following uptake by plants or ingestion by animals. The parent acid herbicides may form conjugates in plants and are more readily excreted by animals than the base-neutral herbicides. Base-neutral herbicides include amides, carbamates and dinitroanilines. These herbicides have relatively low water solubilities compared to acidic herbicides and are more likely to accumulate in fatty tissues. The choice of analytical methods will depend on whether determination of the parent compound is sufficient to meet the study objectives, or whether the suite of target compounds should include hydrolysis products, metabolites, and conjugates.

### 2.4 Multiresidue Methods

There is generally a need to analyze biota samples for residues of not only the parent herbicide but also of metabolites and/or degradation products. Thus, when a method is developed, it is generally multiresidue in nature. In general, this approach tends to be cost-effective, that is, the cost per analyte per sample is low. Other attractive features are that the MRMs are usually rugged and well suited to handle large volumes of samples with relatively short turnaround times, with acceptable levels of performance as defined by the end-use of the data. There are, however, some drawbacks to the use of MRMs that must be evaluated by the analyst and users of the analytical data. When a MRM is used, not all analytes will be extracted from a given matrix with the same efficiency, nor will they respond with the same sensitivity to a specific detector. Thus it is not unusual that a range of detection/quantification limits will result for a given method. In those situations in which analysis of a single analyte is required, rather than develop a new method, the analyst will generally choose or adapt an appropriate existing MRM.
Early MRMs were developed primarily by agrochemical companies for the purpose of providing information to support the registration of pesticide uses. These early methods were heavily focused toward the more stable and low polarity compounds, such as the organochlorine and organophosphorus pesticides, and were designed to quantify the parent compound and a small suite of toxicologically significant byproducts, metabolites, and degradation products. Similar MRMs involving analysis of a few herbicides and their metabolites or degradation products are currently used for research purposes in crop residue studies, toxicological studies, environmental fate studies, etc.

MRMs have been used by regulatory agencies to monitor a broad spectrum of several pesticides, including insecticides, herbicides, fungicides, etc. However, for best results, the MRMs should be optimized for a selected class of compounds. In reality, MRMs for pesticides are usually based on physico-chemical properties of the pesticides and/or analytical approaches, and do not distinguish between herbicides and other pesticides. Thus, methods commonly used for insecticides and other pesticides can also be used for herbicides. Some of the current MRMs, however, do not include acidic herbicides in the suite of pesticides monitored. Acidic herbicides require pH adjustment of the aqueous homogenate for efficient extraction, as well as derivatization prior to determination by GC.

2.5 Unknown Analytes

The strategies adopted for the analysis of herbicide residues in biota fall into two main categories, namely cases where only analysis for one or more specific herbicides is required and authentic standards are available. The second case is where the identity of a peak in a chromatogram is unknown and authentic standards may not be available. For the latter, the results may be based on tentative identifications and follow-up analysis may be conducted for possible transformation products.

When analysis of specific target analytes is required, as in the case of residue determinations on sprayed crops, the options for sample extraction and clean-up available to the analyst can be optimized to give the highest recoveries for the chosen compounds. The instrumental analysis, usually employing a chromatographic separation, can be optimized to give maximum resolution between closely eluting compounds. Specific detectors are generally used in these situations. In recent years, MS detectors have been more commonly used, particularly as these detectors have become less expensive and easier to maintain. For a small subset of possible target analytes, the level of effort necessary to confirm that a given analyte, rather than an interfering substance, has actually been detected will be lower than in the case where it is not known which herbicides and metabolites/degradation products may be in the sample.

When it is not known which analytes are in the sample, as in the case of many environmental monitoring studies, compromises must be made to ensure that a wide range of herbicides and their metabolites and degradation products can be extracted and isolated from the matrix components. The recoveries of some compounds will not be as high as in the optimized methodology for known target analytes but will be sufficiently high to be quantifiable with a given degree of confidence. MS or atomic emission detection (AED) is desirable in this case because these detectors not only provide quantitative data but will give qualitative information which can be used for confirming the presence of an analyte in the sample.

2.6 Miniaturization of Methodology

There is growing concern about the amount of reagents, solvents, and contaminated water released to the environment as a result of analytical operations. Steinwander has estimated that such operations release a factor of 10^8 more materials to the environment than the amounts of residues being determined. The benefits of herbicide residue analytical programs – reduction of the detrimental effects of herbicide use on the environment and human health through improved understanding of the levels, distribution, fate and effects of these substances – should not be negated by the detrimental effects of laboratory chemicals released into the environment as a result of these programs. Wan and Wong have argued that the issues of solvent consumption and increased environmental impact of proposed analytical methodologies should be as important as those of sensitivity and accuracy. Thus strategies which limit or reduce the consumption of reagents and solvents and the generation of contaminated wastewaters are being adopted. This is due in part to safety considerations in reducing the exposure of laboratory personnel to hazardous substances and the relatively high cost associated with disposal of waste solvents. Presently, disposal costs for solvents and contaminated solutions (water plus solvents) can equal or exceed the original purchase price of the solvents.

There is a growing trend to extract smaller samples, and utilize miniaturized apparatus for sample extraction procedures. Micro methods can reduce solvent and reagent use by a factor of 10 to 100 over conventional methods. Proportionally less solvent is required for methods that use 1 to 5 g of sample instead of the 20 to 100 g used in conventional methods. As well as using less solvent, the resulting micro methods generally
tend to be cheaper, faster, less labor-intensive and more amenable to automation using on-line techniques than conventional methods. However, this approach demands higher instrumental performance and lower detection limits. Other approaches include: the use of a single extraction rather than exhaustive multiple extractions; clean-up and analysis of an aliquot of an extract rather than using the whole extract; use of combined extraction and clean-up techniques; and the elimination of the clean-up step by use of a highly selective instrumental method.\(^{(8)}\)

2.7 Performance Criteria for Analytical Methods

Government regulatory agencies will often dictate minimum performance parameters for analytical methods to be used to determine herbicide residues in commodities and food products. The levels of residues in food are monitored for two purposes: to enforce regulations on acceptable levels, and to estimate dietary intakes. These two programs make different demands on analytical method performance, especially method detection limits.

Regulatory monitoring programs require analytical methods that can detect pesticide residues at or below a stated maximum residue limit (MRL). This limit, sometimes called a tolerance, is the legal maximum concentration of a particular pesticide, metabolite or degradation product allowed in a particular commodity or food. Although national regulatory agencies set their own MRLs, many agencies attempt to set their MRLs to the same levels as the Food and Agriculture Organization/World Health Organization (FAO/WHO)-Codex Alimentarius Commission\(^{(9)}\) in order to facilitate international trade.\(^{(10)}\) MRLs typically range from 0.001 to 110 mg kg\(^{-1}\) in Canada,\(^{(11)}\) 0.1 to 50 mg kg\(^{-1}\) in the United States,\(^{(12)}\) 0.05 to 70 mg kg\(^{-1}\) in European countries,\(^{(13)}\) and 0.02 to 50 mg kg\(^{-1}\) in Japan.\(^{(14)}\)

For regulatory monitoring, it is desirable that the method detection limit for a particular herbicide be at or below the MRL. Detection limits are variable and depend upon the particular herbicide, commodity, choice of sampling and subsampling methods, and choice of analytical method. Detection limits for methods used for regulatory monitoring in the United States range from 0.005 to 1 mg kg\(^{-1}\), although 0.01 mg kg\(^{-1}\) is a typical value. Detection limits are usually well below the MRL for any particular combination of herbicide and commodity.\(^{(12)}\) Using Belgium as being typical of European countries, the method detection limits range from 0.02% to 100% of the MRLs.\(^{(13)}\)

Total diet studies require detection limits to be as low as practically possible to give accurate information on dietary residue intakes. Detection limits for analyses used in these studies are 5 to 10 times lower than those used for regulatory monitoring, and in general are about 0.001 mg kg\(^{-1}\).\(^{(12)}\) Detection limits can be lowered by a combination of larger sample size and smaller final extract volume,\(^{(13)}\) a larger injection volume for chromatographic methods, use of higher efficiency columns for chromatographic separations or a more sensitive detector.

2.8 Sampling Biota

In brief, there are two main approaches commonly used for sampling biota, namely judgmental or intuitive sampling and statistical or probabilistic sampling. Judgmental sampling is nonstatistical and is based only on the judgment of the person(s) choosing the samples or devising some process to do so.\(^{(15,16)}\) It can be most effective when there is prior knowledge of the sampling site based on historical data or experience of the sampling site in question. Statistical sampling is based on random sampling of a population and, in general, provides a statistical basis for making predictions and inferences about a large target population based on data from a relatively small number of samples.\(^{(15,17)}\) Random sampling requires the largest number of samples, whereas judgmental sampling incorporates the greatest amount of bias. Often a combination of judgmental and random sampling becomes the most feasible approach in order to control costs but still obtain as much useful data as possible.

When designing protocols for sampling plants and animals in the field, many factors have to be considered including large variations within study populations, inhomogeneities in matrices and in the distribution of the analyte within a matrix, and biological processes such as metabolism and conjugation, bioaccumulation and the efficiency of uptake of individual organisms.\(^{(2)}\) The overall sampling protocol may also be influenced by the choice of analytical method, the sampling device, the type of sample container, and possible deterioration (for example, biologically mediated reactions, thermal instability, photodegradation, etc.) of analytes of interest.

2.8.1 Sample Handling in the Field

Appropriate care must be taken in the field to avoid compromising sample integrity. QA/QC protocols must be established for sampling procedures to account for sample preservation, sample transportation and storage, collection of field blanks, field background or control samples, fortified field control samples, and for subsampling. The field QC samples should be handled in exactly the same manner as the environmental samples. QA/QC measures taken to safeguard the confidentiality and chain of custody of samples should be documented and this is mandatory where possible litigation may be an issue of concern. This requirement for good
documentation also extends to situations in which judgmental sampling is performed. For a full discussion of these factors the reader should consult reviews available in the literature.\(^2,18\)

2.8.2 Sampling Plants

Herbicide residues in plants may result through direct application to the plants, or be present as inadvertent residues as a consequence of herbicide transport. Both situations require different considerations in planning appropriate field sampling. In the case of direct application of herbicides, the type (pre- or post-emergence) and method of application will be known and thus some idea of the uniformity of the application. In addition, the rate of application, the growth stage of the crop at application, the interval between application and sampling, and other pertinent information such as rainfall or irrigation after application will be known. Because of such information, crop sampling will most likely be a combination of both judgmental and statistical approaches.

In cases of inadvertent residues, a lower level of contamination and a less uniform distribution of the herbicide can usually be assumed compared to those resulting from agricultural applications. Although the analyte may be unknown, symptoms of phytotoxicity may identify the mode of action of the herbicide and, thus, possibly the herbicide class to which it belongs. In these situations where information is much more limited, or in situations involving litigation and sampling for legal purposes, the approach to sampling would most likely be more statistical in nature so that personal bias is minimized.

2.8.3 Sampling Animals

A fundamental difference between plants and animals for sampling purposes is that animals are mobile. Sampling protocols for animals must therefore account for factors such as movement into and out of areas of exposure, migration patterns, and feeding, spawning, or other periodic activities that could affect the level of exposure and the concentration and location of residues in the organism.\(^2\) Because of such factors, approaches in animal sampling will most likely be more judgmental than statistical in nature.

Proper attention must be given at the study design stage to ensure that all procedures adopted are humane, particularly where the animal must be killed. Likewise due care must be given to the medical ethics pertaining to the sampling procedures to ensure that the overall program is based on sound and defensible science. Furthermore, where the collection of body fluids is necessary, the sampler must exercise due care and attention to safety procedures to avoid infectious diseases.

2.9 Extraction, Derivatization and Clean-up

2.9.1 Considerations in the Analysis of Plant Tissues

Herbicide residues, and residues arising from metabolites or degradation products, can be present as foliar deposits on plant surfaces or, following uptake by the plant, as residues within plants. Depending upon the data required, either type of residue or both could be determined. In situations where both surface deposits and residues taken up by plants are required, two samples are generally analyzed. One sample would consist of intact plants or plant parts for surface deposit determination, and the other would consist of milled/chopped tissue to determine both surface deposits plus residues taken up by plants. The difference between the total residues and surface deposits would be equivalent to the residues taken up by the plants.

Plant surface deposits can include the parent herbicide, photodegradation products, and metabolites formed by enzymatically catalyzed reactions. Residues that occur within plants as a direct result of plant uptake can include the parent herbicide and possibly metabolites or photodegradation products formed on the plant surface. Subsequent to uptake, residues can also include metabolites produced by enzymatically catalyzed reactions such as oxidation, reduction, hydrolysis and conjugation.\(^19,20\)

Unlike the nonsynthetic reactions of oxidation, reduction and hydrolysis, conjugation involves the reaction of the herbicide or metabolite/degradation product with endogenous plant substrates. Conjugation with plant substrates is quite common because these reactions are used by plants to deactivate or detoxify herbicides. Common conjugation reactions include the reaction of acidic herbicides with sugars to form an ester linkage,\(^19,20\) formation of amido linkages with amino acids, and glutathione conjugation. Unlike the glutathione conjugates, the ester and amide conjugates can be cleaved by hydrolysis to release the parent herbicide.

In choosing an appropriate solvent system for the extraction of residues, one of the first considerations of the analyst in developing a method, or choosing/adapting an existing method, is whether the parent herbicide and its metabolite/degradation product(s) include acidic compounds, base-neutral compounds, or both. When acidic herbicides/metabolites/degradation products are present, an hydrolysis step can be incorporated to cleave possible conjugates. In contrast, base-neutral herbicides can be extracted from plant tissue with a number of organic solvents including acetone, hexane, diethyl ether, dichloromethane (DCM), ethyl acetate (EtOAc), acetonitrile (ACN), methanol (MeOH) and ethanol (EtOH). As the moisture content of the plant tissue increases, water miscible solvents are preferred.
Since benzene and chloroform are suspected carcinogens, these solvents are seldom used in current analytical methods. When both acidic and base neutral herbicides/metabolites/degradation products are present, a basic aqueous extraction solution is generally employed. Base-neutral analytes can be removed from the basic extract by liquid–liquid partitioning (LLP) with an appropriate organic solvent. After acidification of the aqueous extract, the acidic analytes can be isolated also by partitioning with an appropriate organic solvent.

The majority of crops used for human or livestock consumption are generally low in oil or lipid content. Thus, analytical methods to determine pesticide residues in such crops generally do not require clean-up procedures for lipid or oil removal. However, some MRMs include a clean-up step for lipid and pigment removal regardless of the matrix being analyzed. In those crops grown for their oil (canola, flax, sunflower, soybean, etc.), clean-up for lipid content is usually only required for analysis of the seed, the plant component in which the oil is most concentrated. Table 1 presents types of foods and commodities grouped by water and fat content. Although plant and animal tissues share many matrix components, plants contain significant levels of matrix co-extractives not found in animal tissues which can interfere with herbicide residue analysis unless appropriate clean-up procedures are employed. Such co-extractives include pigments, such as chlorophyll, and alkaloids.

Since benzene and chloroform are suspected carcinogens, these solvents are seldom used in current analytical methods. When both acidic and base neutral herbicides/metabolites/degradation products are present, a basic aqueous extraction solution is generally employed. Base-neutral analytes can be removed from the basic extract by liquid–liquid partitioning (LLP) with an appropriate organic solvent. After acidification of the aqueous extract, the acidic analytes can be isolated also by partitioning with an appropriate organic solvent.

The majority of crops used for human or livestock consumption are generally low in oil or lipid content. Thus, analytical methods to determine pesticide residues in such crops generally do not require clean-up procedures for lipid or oil removal. However, some MRMs include a clean-up step for lipid and pigment removal regardless of the matrix being analyzed. In those crops grown for their oil (canola, flax, sunflower, soybean, etc.), clean-up for lipid content is usually only required for analysis of the seed, the plant component in which the oil is most concentrated. Table 1 presents types of foods and commodities grouped by water and fat content. Although plant and animal tissues share many matrix components, plants contain significant levels of matrix co-extractives not found in animal tissues which can interfere with herbicide residue analysis unless appropriate clean-up procedures are employed. Such co-extractives include pigments, such as chlorophyll, and alkaloids.

### 2.9.2 Considerations in the Analysis of Animal Tissues

Animals are only indirectly exposed to herbicides, usually through contact with herbicide drift or by ingesting contaminated food and water. Herbicides generally have low to moderate toxicity to mammals and other animals because the herbicides and/or their metabolites are readily metabolized or excreted. Thus, because herbicides generally do not bioaccumulate in animals, sampling animal tissues for herbicide residue determination has not been a priority from a regulatory point of view. Herbicide residues in animal tissue used for human consumption are thus rarely looked for unless an animal (livestock) has been directly sprayed or has eaten contaminated feed. However, in ecotoxicology and environmental fate studies, herbicide residues have been determined in the tissues of several organisms (for example, birds, fish, mussels, benthic and terrestrial invertebrates), especially those which may serve as bioindicators of herbicide exposure.

Extraction of animal tissues can be complicated by interferences from lipids and fatty acids (present as di- and triglycerides) as well as minor components such as sterols. Thus appropriate clean-up procedures must also be employed for these matrices. Animal tissues are generally classified according to the level of moisture and the amount of fat; such considerations affect the choice of the appropriate analytical method. Low moisture samples have less than 75% water. Low fat samples have less than 2g of fat per 20 to 100g of sample. Using these criteria, muscle tissue is low fat–low moisture, whereas lard, fat, blubber and adipose tissue are high fat–low moisture.

### 2.10 Instrumental Determination

There are several factors to consider in the selection of an instrumental method for the determination of herbicide residues in biota. The choice is usually governed by the availability of instrumentation in a laboratory, the human resources for conducting the analyses, including the level of training and expertise required for operation of an instrument, the need to meet specified detection limits and turn around times, and the overall cost of the analyses.

Earlier MRMs have relied largely on GC with selective detectors, such as the nitrogen–phosphorus detector (NPD), the Hall electrolytic conductivity detector (HECD), the flame photometric detector (FPD) and the electron capture detector (ECD). More recently, MRMs have incorporated the use of MS detectors which provide much greater specificity and essentially equivalent sensitivity. Because of the increased specificity provided by the MS detectors, larger numbers of compounds can be analysed in a given sample extract. It is not unusual for regulatory agencies to use a MRM based on automated MS detection to screen greater than 100 analytes.
3 SAMPLING

The quality of the determination of the levels of herbicides in biota is only as good as the “weakest link in the chain”. This weakest link, in general, is often the wide variance associated with field sampling compared to the variance introduced by laboratory procedures. In the past, this fact was grossly overlooked in the scientific literature. More recently, however, there has been increasing attention given to sampling, as evidenced by several excellent reviews on sampling procedures for a wide range of environmental matrices, including biota.(2,15,17,18,23,24)

3.1 Sampling Plants

3.1.1 Sampling Treated Crops

In general, only the portions of the crop plant utilized for human or livestock consumption are sampled for residue analysis. This may include roots or tubers, bulbs, leaves and stalks, seed and fruit from trees, bushes and vines. The manner in which field sampling is carried out will be determined largely by the type of crop grown, the part of the plant to be analyzed, the objectives of doing the analyses and the size of the plot or number of plants available for sampling. For example, the number of treated trees or bushes available for sampling may be limited and thus dictate how many individual fruits are sampled from each tree or bush. Use of small field plots may require that the entire plot or complete center rows (to avoid edge effects of spraying) be used to get sufficient sample size. Use of larger plots will require the random collection of samples, each of which could be a defined length of row, a defined area, or individual plants at a defined sampling frequency. In some instances, these samples could be combined to form composite samples. Larger plots are also required when multiple samplings are necessary to monitor herbicide dissipation in the crop over time (for example, the complete growing season). Unless the study has a temporal aspect, samples are usually collected when the crop would normally be harvested for human or livestock consumption. Foliar portions of plants may be cut at the soil surface or at a given height to simulate normal harvest procedures.

3.1.2 Sampling Environmentally Contaminated Plants

The most common source of inadvertent residues in crops or other vegetation is from atmospheric deposition of herbicide drift. Contamination occurs downwind of the herbicide application and damage to nontolerant plants is often characterized by the browning/yellowing, spotting or deformation of leaves.

Since a major objective is to confirm the presence of the herbicide in the matrix of interest, sampling is generally carried out in a manner to maximize the probability of detecting the herbicide. Thus, because of possible dissipation losses of the relatively small amounts of herbicide involved, sampling should be conducted as soon as possible after deposition occurs or as soon as plant damage is observed. The extent of crop or plant damage and the fact that environmental residues decrease with distance from the application can also be determinants in how sampling is carried out. Generally, leaves, which make up the greatest surface area of plants, are randomly sampled for extraction and analysis. In the case of coniferous plants, the needles, which have been shown to be efficient collectors of atmospheric pesticide residues, are sampled for analysis.

3.1.3 Sample Handling in the Field

Once representative field samples have been collected, precautions must be taken to maintain their integrity. Control and treated samples are usually kept separate to prevent possible cross-contamination of the controls. Generally, samples are protected from sunlight to prevent photodegradation of foliar deposits and to slow further metabolism by the plant. Immediately after collection, samples are generally placed in a cool environment, usually near 0°C, to slow possible metabolism and microbiological processes. Although sample extraction immediately after collection would be preferred, samples can seldom be accommodated in such a manner and therefore must be maintained at −20°C or lower to minimize metabolic and microbial processes. The interval between sample collection and deep cooling is usually kept to a minimum to maintain the integrity of the sample until extraction.

Generally, matrices of high moisture content are collected into polyethylene bags or aluminum foil-lined paper bags which help to maintain the moisture content of the sample. Relatively dry matrices can be collected into paper or cotton bags, cardboard boxes, or wooden boxes/crates. These matrices are generally further dried prior to milling and such containers facilitate air-drying.

3.1.4 Representative Subsamples for Residue Analysis

In situations in which the field sample is quite large (for example, several kilograms), it is necessary to take a subsample representative of the field sample. Generally, the subsample is large enough to permit duplicate analysis, if required. In most cases, the matrix is prepared for subsampling as it normally would be used for human or livestock consumption. For example, carrots and beets would be washed to remove soil particles, oranges and cooking onions peeled, the bracts removed from strawberries, and lettuce and celery trimmed. For
In the latter case, relatively low temperatures (30 to 40 °C) are preferred to prevent volatilization or thermal decomposition of herbicide residues. Dry ice is often employed during the milling process to cool the mill and prevent possible thermal decomposition of herbicide residues within the matrix. The mill is generally cleaned between samples, using a blast of forced air, to prevent cross-contamination between subsamples.

**3.1.4.2 Low Moisture Content Matrices**  
Subsamples with relatively low moisture content are generally allowed to air dry or may be dried in a forced-air oven to facilitate milling using either a Wiley mill or a hammer mill. In the latter case, relatively low temperatures (30 to 40 °C) are preferred to prevent volatilization or thermal decomposition of herbicide residues. Dry ice is often employed during the milling process to cool the mill and prevent possible thermal decomposition of herbicide residues within the matrix. The mill is generally cleaned between samples, using a blast of forced air, to prevent cross-contamination between subsamples.

**3.2 Sampling Animals**

The key to representative sampling of fish, birds, insects and other animals for herbicide residues is effective planning prior to conducting the field program. Detailed knowledge of variables such as the migration routes of birds, the life cycles of insects, and the behavior patterns of the animals or fish species being studied may be required. The number and frequency of sampling events to account for seasonal variations in time and space may have to be determined. Decisions regarding what constitutes a representative sample and the appropriate number of samples to meet study objectives will have to be made. Careful attention must be given to the type of sample containers, the sampling technique employed to avoid cross-contamination between samples, appropriate sizes and number of coolers, and contingency plans for timely transportation to the testing laboratory to minimize the uncertainty associated with compromising sample integrity.

For investigations requiring sampling of live specimens of either animals or human beings, sampling procedures must be humane and be as nonintrusive as possible. Exposure to herbicides is often assessed indirectly by sampling body fluids such as urine, milk, blood or feces for residue analysis. Such sampling of live specimens generally requires the presence of a professional from the veterinary or medical disciplines. However, other less intrusive samples, for example, dermal patches and inhalation samplers, used for assessment of exposure of farmers during field application of herbicides, can also be collected.

**3.2.1 Sample Handling in the Field**

Precautions to be taken to avoid compromising sample integrity during sampling are similar to those described for sampling plants. Since judgmental sampling is frequently performed (for example, the collection of dead fish following a fish-kill accident, or sampling selected birds and/or eggs following a spill in the impacted area), it is particularly important that control samples are also collected from nonimpacted areas to establish background levels of the herbicides.

**3.2.2 Representative Subsampling for Residue Analysis**

Following field sample collection, representative subsamples may be taken in the laboratory for extraction and instrumental analysis. The type of subsamples taken will depend on the objectives of the study. For example, if there is a need to address human health and safety issues pertaining to consumption of meat, then muscle tissue and other edible portions of the animal would be subsampled. In contrast, for assessment of the environmental exposure of seals to herbicides, for example, the blubber which contains lipid-rich tissue and is therefore expected to be a sink for organic contaminants would be subsampled. For similar reasons, sampling of the lipid-rich tissue in marine or fresh water shrimp, mussels or clams would also be favored over analysis of the whole animal. The latter two animals are known to be fairly localized and not move over large distances within a given area and thus can serve as good integrators of contaminants over a period of time. The change in levels and distribution of contaminants within the organism with age can also be collected.

**4 EXTRACTION, DERIVATIZATION AND CLEAN-UP**

This section describes the most common techniques employed to extract and derivatize herbicide residues, and clean-up extracts for subsequent instrumental determination. While these techniques are discussed...

In separate subsections as though they are distinct operations, the distinctions between extraction and clean-up have become blurred by the use of techniques in which these operations are combined and performed simultaneously.(25)

Table 2 summarizes selected methods available for the extraction and clean-up of residues of some herbicide residues from plants. For more details about the techniques discussed below, the reader should consult one of the several excellent reviews which have appeared in the literature.(21,26–28)

### 4.1 Extraction of Plant and Animal Tissues

The term “extraction” in this context refers to the transfer of herbicide residues from the solid sample matrix to the extracting liquid phase, usually an organic solvent, while leaving most of the bulk matrix behind. Some of the
operations involved include homogenization, filtration and LLP. The latter operation involves partitioning solutes between two immiscible liquid phases, usually by shaking in a separatory funnel. Solute partition between the two phases depending on their relative solubilities in the solvents.

In many of the methods currently in use, tissue samples are first blended with a water-miscible solvent such as ACN or acetone. Such solvents have become popular because a large number of different herbicide residues can be extracted without also extracting large amounts of lipids which can cause problems later in the determination. The raw extract is then filtered to remove suspended tissue, and the aqueous filtrate partitioned against a water-immiscible organic solvent to transfer the herbicide residues to the organic phase. This approach is termed “shake-filter extraction” or “liquid–liquid extraction”. A second technique, which replaces LLP with liquid–solid partitioning, is termed “solid-phase extraction” (SPE). A third approach is to mix and grind the homogeneous solid sample together with a granular solid phase material, usually alumina (aluminum oxide), and sodium sulfate. The extract is dried over anhydrous sodium chloride is usually added to the mixture to aid in phase separation. The advantages of this approach include: extraction, partitioning and removal of water in one step; and the possibility of method miniaturization. Further details can be found in the reports by Steinwandter which review modern pesticide extraction methodologies.

Fatty tissues, such as those in fish, are often extracted by blending the tissue with a mixture of light petroleum and sodium sulfate. The extract is dried over anhydrous sodium sulfate, the solvent evaporated, and then subjected to a clean-up step, typically LLP or gel permeation chromatography (GPC; see below) to isolate the herbicide residues.

4.1.1 Shake-filter Methods

The simplest and most common methods of extracting herbicide residues from tissues are the shake-filter methods. They are applicable both to residues on plant surfaces and to incurred residues in plant and animal tissues.

Herbicide residue deposits on plant surfaces are removed either by rinsing the plant surface with a stream of solvent or by submerging the whole plant or plant part in a suitable solvent. The choice of solvent is based on the solubility of the herbicide or its metabolite/degradation product(s), and whether or not it is the intention to remove herbicide residues present in plant cuticular waxes. In the latter case, n-hexane or DCM are frequently used. If not, MeOH, EtOH or aqueous solutions of these alcohols have been used. The contact time of the plant tissue with the solvent is generally kept short (5 min or less) to minimize extraction of herbicide residues (apart from residues on the surface) taken up by the plants. Subsequent to extraction, the resulting solvent wash is subjected to any necessary clean-up or derivatization steps, and concentrated to a suitable volume prior to analysis and quantification of the residues.

The extraction of herbicide residues from plant or animal tissues, either chopped or milled, requires mechanical disruption of cell membranes using processes such as sonication, blending or homogenization in an organic solvent or aqueous-organic solvent mixture, or a dilute acidic or basic aqueous solution. Extraction recoveries, in some cases, can be further enhanced by shaking (in a sealed container), heating or refluxing. The extract is then separated from the solid matrix by centrifugation, decanting, filtration, or a combination of these. The most common approach is to homogenize the tissue sample with the extracting solvent mixture. The homogenate is then either filtered prior to LLP to isolate the residues, or centrifuged prior to the removal of the supernatant containing the isolated residues.

MRMs commonly use so-called “universal extraction solvents” to extract and isolate herbicide residues, MRMs include: extraction, partitioning and removal of water in one step; and the possibility of method miniaturization. Further details can be found in the reports by Steinwandter which review modern pesticide extraction methodologies.

4.1.2 Solid-phase Extraction

SPE involves the partitioning of solutes between a stationary solid phase and a mobile liquid phase. Two basic forms of SPE exist: normal-phase, in which the stationary phase material, usually alumina (aluminum oxide), Florisil® (a manufactured coprecipitate of magnesium and silicon dioxides containing 16% MgO) or silica gel, interacts strongly with polar components, and eluting solvents are generally of low or medium polarity (e.g.
light petroleum, hexane or DCM); and reversed-phase, in which the stationary phase material is generally a bonded-phase silica gel material, and eluting solvents are of higher polarity (MeOH or ACN). In both forms, fractions are collected with step-wise addition of solvents of increasing solvent strength. Since most samples are homogenized with water-miscible solvents or aqueous solvent mixtures, reversed-phase is the most commonly used form of SPE.

SPE columns can be prepared in the laboratory by placing the granular solid into a column or a syringe barrel made from glass, polyethylene or polypropylene. Alternatively, manufactured SPE cartridges, containing from 100 mg to several grams of sorbent material prepacked into the cartridges, are also available. These disposable cartridges are convenient to use, have a controlled lot-to-lot variability, and can be used in automated sample preparation procedures. The most common granular materials used in SPE are bonded-phase silica gels. The silica gel is coated with a layer of organic ligands that are chemically bonded to its surface. Depending on the nature of the functional group, the selectivity of the extraction can be tailored for different applications. The most common organic functional groups used are C18, octyl (C8) and cyanopropyl (CN).

SPE can be accomplished in two ways as the filtered homogenate is passed through the sorbent bed. In the first case, the stationary phase has a greater affinity for the herbicide residues in the filtrate than the solvent in which the residues are dissolved. The residues accumulate on the surface of the granular solid while the filtrate with the majority of co-extracted matrix components pass through unadsorbed. The herbicide residues can then be eluted with a second, stronger solvent, producing a concentrated solution with a minimum of interfering matrix components. In the second case, the stationary phase retains the majority of the co-extracted matrix components while the herbicide residues elute with the solvent. For example, SPE columns containing C18 bonded-phase silica gel are often used to retain fats and lipids while facilitating the extraction of pesticides by the eluting solvent.

SPE has been used to replace the LLP step of shake-filter extraction procedures. Casanova has reported the use of C18-SPE in the Luke MRM extraction procedure for the determination of organochlorines and organophosphates in high moisture–low fat foods. Hopper used a different SPE approach to replace the LLP step of the Luke procedure. A column containing a bed of Hydromatrix® (a specially prepared pelletized form of diatomaceous earth) is conditioned by eluting in sequence: 0.1 M KH2PO4 buffer, acetone and DCM. The aqueous acetone sample extract is then added to the column, where water separates from the DCM–acetone mixture and is absorbed by the solid support. The column is then eluted with DCM. These approaches save time, eliminate the emulsions typical of LLP, offer batch processing, and combine extraction and clean-up into the same operation.

4.1.3 Matrix Solid-phase Dispersion

MSPD, sometimes referred to as “column extraction” has been used to extract pesticide residues from fruits and vegetables and from animal tissues. The sample is ground together with the solid support, the mixture packed into a column, and residues eluted with a suitable solvent. The solid supporting material can be either a relatively inert material such as anhydrous sodium sulfate or diatomaceous earth, or a material chosen to give some selectivity to the partition and extraction of the herbicide residues. Solid sorbents such as alumina or Florisil, or bonded-phase silica gels, are commonly used. In some applications, the tissue–sorbent mixture is placed into a column prepacked with another adsorbent such as Florisil to absorb additional co-extracted material and combine extraction and clean-up in the same step. This approach combines homogenization and partition into one step, eliminating the need to filter a liquid homogenate. It also uses less solvent, is less labor intensive and faster than conventional liquid–liquid extraction methods.

4.1.4 Supercritical-fluid Extraction

SFE is one of the most promising alternatives to the conventional methods of residue extraction. It takes advantage of the unique solvating properties of supercritical fluids to reduce greatly the use of toxic organic solvents. A supercritical fluid is formed when a substance is heated and pressurized to its critical state in which the density of the liquid and gas phases are the same. This combination of critical temperature and critical pressure is referred to as the critical point. At temperatures and pressures at or above the critical point, a substance is neither a gas nor a liquid but a dense fluid with some of the properties of both. The critical point of CO2, which is commonly used for SFE, is 31.3 °C and 7.38 MPa.

Typically, the sample is ground up with or dispersed on a medium such as diatomaceous earth or anhydrous sodium sulfate and transferred to a stainless steel extraction cell. The extraction cell is then placed in an oven and a pump delivers supercritical fluid to the cell at pressures generally ranging from 10 to 70 MPa. The fluid with the extracted analytes passes through a restrictor and depressurizes into a collection vial or other analyte trapping region. When the supercritical fluid is depressurized, the resulting gas has no solvating power,
and the extracted solutes dissolved in the supercritical fluid precipitate out and can be easily collected.

SFE has many advantages over traditional extraction techniques. Highly selective extractions can be made with control of fluid density and the addition of modifiers such as MeOH, ACN or water. Supercritical fluids have lower viscosities and higher diffusivities than liquid organic solvents. The lower viscosities lead to better penetration of matrix pores and interstitial spaces and higher diffusivities lead to faster molecular diffusion. Both properties lead to faster and more efficient extractions. The extraction can be selective, automated and can be successfully used to extract thermally labile compounds. In addition, SFE can be placed on-line with GC or HPLC. When supercritical CO2 is used, the extraction fluid is relatively non-toxic. Disadvantages include extraction efficiencies that can be matrix dependent and different recoveries obtained for fortified analytes versus aged or incurred analytes. The high pressures utilized in SFE require special safety precautions.

A few reports have reviewed the methodology and approaches to method development. The factors controlling SFE of environmental samples, which also apply to the extraction of biological samples, have been reviewed.

4.2 Derivatization of Plant and Animal Tissue Extracts

Derivatization can be incorporated into a method at different points in the procedure. The herbicide residues can be derivatized as part of the sample preparation step, or on-line after separation on an HPLC column. This latter technique is often referred to as “post-column derivatization”. Derivatization may be performed to render analytes more suitable for GC analyses by increasing volatility and thermal stability. Derivatization may also facilitate confirmation and increase sensitivity to specific detectors. Most current methods do not incorporate derivatization reactions in the sample preparation step prior to instrumental determination because these reactions can be time-consuming and can produce unwanted interferences due to side-reactions. In some situations, improvements in chromatographic resolution, such as the adoption of capillary columns in GC, and the use of HPLC, MS detectors and immunoassays have made derivatization reactions unnecessary.

A notable exception to the trend away from pre-analysis derivatization is the use of esterification reactions to convert acidic herbicides such as phenoxyalkanoic, aryloxyalkanolic, benzoic and picolinic acids into their more volatile esters for GC analysis. Methyl esters, generated using a boron trifluoride/MeOH reagent or diazomethane, are frequently utilized. If co-extractives interfere with the methyl esters, higher molecular weight esters, such as the propyl or butyl esters, can be utilized. To enhance sensitivity to specific detectors, reagents containing 2-chloroethanol, trifluoroethanol or pentafluorobenzyl bromide are also available to form the analogous alkylated derivatives.

Post-column derivatization has proven useful in HPLC analyses of certain analytes such as N-methylcarbamates which cannot be detected with sufficient sensitivity by commonly used ultraviolet/visible (UV/VIS) absorbance detectors. Kok and Heimstra developed a method that uses a solid-phase catalyst in a heated metal column to hydrolyze the analytes, followed by reaction with a o-phthalaldehyde–2-mercaptoethanol reagent to produce derivatives that can be detected by a fluorescence detector with great sensitivity.

Derivatization techniques and their applicability to pesticide residue analyses have been reviewed.

4.3 Clean-up of Plant and Animal Tissue Extracts

In addition to herbicide residues, sample extracts also contain co-extracted matrix components, some of which may interfere in the analysis and quantification of the analytes. Matrix components can accumulate in GC injectors or be retained on GC or HPLC columns and decrease the resolution of chromatographic separations. For these reasons, it is generally necessary to remove co-extractives from tissue extracts using clean-up techniques. Unfortunately, there are also disadvantages to clean-up procedures. Not only do they add time and expense to the analyses, analyte losses may be incurred which can be unpredictable in some matrices. With the addition of clean-up procedures to MRM’s, compromises are often made which can lead to poor recoveries for some analytes.

4.3.1 Liquid–Liquid Partitioning

LLP is commonly used as a group separation technique to fractionate on the basis of herbicide classes or to clean-up samples prior to analysis. The main disadvantages of LLP are the use of relatively large volumes of solvent, and the formation of emulsions which can be time-consuming to break. In many methods, LLP has been replaced by SPE techniques.

Light petroleum extracts of fatty tissue can be partitioned against ACN that is saturated with light petroleum. The more polar pesticides partition into the ACN layer, leaving the nonpolar lipids in the light petroleum layer. The ACN is mixed with water and sodium chloride, back-extracted with light petroleum, and dried over anhydrous sodium sulfate before further clean-up.

LLP has proven to be very useful for the clean-up of basic extracts of biota tissue for determinations of...
acidic herbicides. The basic extract is first extracted with an organic solvent to remove base-neutral compounds. The aqueous phase is then made acidic (pH < 2) by the addition of sulfuric or hydrochloric acid. The neutralized acids are then back-extracted into DCM or diethyl ether. The solvent layer may be washed with distilled water prior to drying over anhydrous sodium sulfate before concentration and derivatization.

4.3.2 Gel Permeation Chromatography

GPC, also known as size exclusion chromatography, separates components on the basis of molecular size. The GPC resin, which contains a narrow distribution of pore sizes, is slurry-packed into a column using the eluting solvent. Prior to packing, the GPC resin is allowed to swell in the eluting solvent. The sample extract is dissolved in the elution solvent and is added to the top of the column. Large molecules such as lipids, which have molecular weights in the range 600 to 1500 Daltons (atomic mass units), are not able to enter the pores of the resin so they move through the column with the elution solvent and are eluted first. The smaller analyte molecules, which are typically 200 to 400 Daltons, can enter the pores and thus elute more slowly than the larger molecules. The flow of the eluate from the column is diverted to waste while the lipids and other co-extractives are eluting from the column, after which the smaller analytes are collected. A single column can be used for many samples before its performance deteriorates. The performance and calibration of the column is checked using corn oil fortified with pesticides. GPC clean-up of samples is usually performed in batches of 20 or more using an automated system, such as the Autoprep (OI Analytical).

The original GPC method developed by Stalling et al. used 2.5-cm internal diameter columns. Reports by Patterson and van Rijn and Tuinstra have described the use of 1-cm and 2-mm internal diameter columns, respectively. The main benefit of these modifications was to reduce solvent consumption. Other advantages include a reduction in the amount of resin required, and smaller elution volumes. One disadvantage of the modifications is a decrease in the amount of fat that can be retained by the column. However, with the trend to smaller sample sizes, this should not be an impediment to the use of smaller columns.

4.3.3 Solid-phase Extraction

The principles of SPE for the clean-up of extracts are essentially the same as described above under extraction techniques. One of the most frequent uses of SPE is the removal of lipids from extracts of biota using a column of Florisil®. Silica gel columns are often used to further clean-up fractions collected from Florisil® columns.

5 INSTRUMENTAL DETERMINATION

Following the extraction, derivatization and clean-up steps, common instrumental analyses are used for the determination of herbicides and their degradation products in extracts of both animal and plant tissues. The most common separation techniques used are GC and HPLC. In recent years, there has been advances in CE, a relatively new technique, providing many advantages over traditional gas and liquid chromatographic separations. Selected examples of instrumental techniques will not be repeated here but are summarized in Table 3. The current most widely used instrumental technique for the determination of herbicide residues is MS coupled to GC or HPLC. This technique provides sensitive multichannel detection of components, with reliable identification and quantification of herbicide residues. These features are particularly attractive for investigations of herbicide residues in complex mixtures containing co-extracted matrix compounds. The MS methods, once optimized, can facilitate high sample throughput at comparatively low cost compared to conventional approaches.

5.1 Gas Chromatographic Separations

GC is a technique for separating volatile and semi-volatile components of a mixture based on differences in distribution or partitioning of substances between...
a stationary liquid phase and an mobile gas phase. The separations take place within a column, usually a fused-silica open tubular (FSOT) column, 0.1 to 0.5 mm internal diameter and 10 to 60 m long. As the separated components elute from the column, they are detected using a variety of detectors to produce a chromatogram. Current gas chromatographs are microprocessor-controlled and are equipped with desktop microcomputer data handling systems. The advantages of GC include the ability to resolve several hundred components in a mixture, excellent quantitative performance, high sensitivity, and ease of use. However, it is limited to compounds that are thermally stable, non-reactive and volatile at typical operating temperatures of 50 to 350°C. Fortunately, most herbicides or their derivatives are amenable to GC separations. There are several detectors which can be utilized for the analysis of herbicides residues in biota. Most give reproducible linear responses over wide dynamic ranges, high sensitivity, are stable and rugged, and have low noise characteristics.

5.1.1 Mass Spectrometric Detectors

MS is generally the detector of choice for selectivity and sensitivity of detection of analytes in extracts of plant and animal tissues. This is largely due to the fact that these detectors can be operated such that the response is either universal (positive response for all compound classes) or selective (very sensitive and specific responses to particular elements or chemical classes). The MS can thus provide information for identification of unknown components. The combination of the separating power of the GC with the identification power of the MS detector and the data handling capabilities of modern desktop computers has produced a powerful instrumental technique for residue analysis. Key characteristics of the MS detector are discussed below.

The differences between MS instruments are mainly in size and functionality, and in the type of mass filter used to separate ions according to mass. Each type has advantages and disadvantages in performance, utility, and cost. MS instruments can be classified as benchtop instruments, or larger, more traditional instruments. Benchtop MS instrumentation has been reviewed by Wach. Generally, benchtop instruments are best suited for routine well-defined applications while larger instruments are better suited for research applications, although the distinction is becoming blurred. Benchtop instruments are usually limited to ion masses less than 1000 and have smaller vacuum pumps which limit the choice of sample inlets and interfaces that can be used. The larger instruments have higher mass range capabilities, more inlet and interface options, and generally higher mass resolution. Benchtop instruments are generally less expensive than their larger counterparts.

Benchtop MS instruments are relatively inexpensive, rugged, easy to use, and employ technology based on either the conventional quadrupole mass filter or the relatively new quadrupole ion-trap. A good example of the former is the quadrupole mass selective detector (MSD) manufactured by Hewlett-Packard. This compact instrument is equipped with an electron impact (EI) source and is optimized for use with FSOT-column gas chromatographs. It has proven very useful for analyses of a variety of organic compounds, including herbicides. The quadrupole ion-trap employs a relatively new technique in which the ionization, mass selection, and detection occur within the same space, but are separated in time. The principles and practice of ion-traps have been reviewed by McLuckey et al. Examples of ion-trap instruments are the Varian Saturn and the Finnigan GCQ. Other instruments use either the conventional quadrupole mass filter, magnetic sectors or time-of-flight mass selection.

The mass spectrometer can be operated in two main modes of detection: full scan mode or selected-ion monitoring mode. In the full scan mode, the MS repeatedly scans from one end of the mass range to the other as components elute from the chromatographic column, creating a collection of mass spectra. The mass spectrum from a single component peak can be used to identify or confirm the component by comparison of the linear range of the mass spectrum of the unknown with that of an authentic standard. In this mode, the linear range of the MS is roughly comparable to that of the flame ionization detector (FID), 100 pg to 100 μg. For quantitative determinations, the mass spectrometer is usually operated in the selected-ion monitoring mode. In this mode the mass spectrometer is tuned to detect only a few ions characteristic of the target herbicides, metabolites, or degradation products. This can result in an increase in sensitivity by a factor of 10 to 100 compared to the full scan mode. In favorable cases, the relative abundances of the ions can be matched with the expected values observed for the authentic standards for both sensitive detection and confirmation in a single instrumental analysis. In the selected-ion monitoring mode, the MS detector can be as sensitive as specific detectors for halogenated compounds, as discussed below.

Tandem mass spectrometry (MS/MS) is a powerful technique for characterizing unknown components in a mixture and providing sensitive, selective detection of trace levels of target compounds. In conventional quadrupole and sector instruments, the first mass filter selects an ion, passes it to a collision cell where further fragmentation takes place, and a second mass filter scans or selects the fragment ions. In the ion-trap, the processes take place in the same volume but are separated in time. The technique provides an added...
dimension of information which can improve selectivity, reduce chemical noise, and increase sensitivity. For example, MS/MS has been used to determine residues of diclofop-methyl and triallate in the lipid-rich tissues of amphipods without prior clean-up or GC separation.\(^{103}\) The high cost and complexity of traditional MS/MS instruments employing quadrupole mass filters and/or magnetic sectors have hampered the widespread adoption of this powerful technique. However, the relatively low cost, ease of use, and sensitivity of ion-trap instruments is expected to result in a wider acceptance of MS/MS techniques for the analysis of organic residues.

5.1.2 Other Specific Detectors

In addition to the MS, the NPD and the ECD are the most frequently used specific detectors for herbicide determinations. The operation of these detectors has been described elsewhere\(^{102}\) and will not be repeated here. Instead, emphasis will be given to examples of herbicide classes for which the detectors are best suited, a summary of which is given in Table 3.

Except for the MS detector, specific detectors have one common disadvantage: they provide insufficient qualitative information for identification of components. Component identification using such specific detectors is based only on a characteristic elution time using a specified column under defined conditions. While acceptable in well-defined situations, such as routine determinations of known compounds in crops or food commodities, the lack of qualitative information is a disadvantage in screening of samples for unknown analytes.

The NPD, sometimes referred to as the thermionic emission detector, is a variant of the FID. It offers improved selectivity for nitrogen- and phosphorus-containing compounds over hydrocarbons. Compared to the FID, the NPD in general has 1 to 2 orders of magnitude greater response for nitrogen-containing compounds and 2 to 3 orders of magnitude greater response for phosphorus-containing compounds. In general, the linear range of the NPD is about 0.1 pg to 1 ng of analyte.

The primary advantages of the ECD is its very high sensitivity (0.1 pg) and high selectivity for herbicides containing halogen atoms (F, Cl, Br, I). Many compounds which do not contain halogens can also be detected by the ECD after derivatization with reagents that add halogen-containing functional groups. The ECD responds with lower sensitivity to oxygen-, sulfur-, and nitrogen-containing compounds as compared to halogen-containing compounds.

Other less commonly used specific detectors include the HECD and the FPD. The HECD can be operated in halogen-, nitrogen- and sulfur-specific modes of operation. However, it has a somewhat limited linear range of about 1 ng to 100 ng. The FPD can also be used for the selective detection of organic compounds containing sulfur atoms as well as phosphorus. In the phosphorus mode, it is linear from about 10 pg to 100 ng. In the sulfur mode, the response is proportional to the square of the quantity of sulfur with a quantification range of about 200 pg to 100 ng.

5.1.3 Atomic Emission Detector

The AED manufactured by Hewlett-Packard is a relatively new instrument with capabilities that complement the MS for determination of herbicides and other organic compounds in a variety of matrices. The GC column effluent is mixed with helium and a small amount of oxygen and introduced into a microwave-induced plasma source operating at 1700 °C. At this temperature, the organic compounds are broken down into their individual elements which are thermally excited and emit light at characteristic wavelengths. The light is dispersed by a monochromator and detected by a photodiode array. Multiple elements can be quantified in one injection, giving information that can be used to determine the empirical formula of each compound. The instrument is also able to distinguish isotopes of some elements, such as deuterium, carbon-13 and nitrogen-15. Combined with MS data, the data from the AED can be used to identify unknown components with great reliability. The detector can provide picogram level detection of elements with a linear response that is largely independent of the molecular structure of the analyte. It is generally more sensitive than the MSD in full-scan mode, five times more sensitive than FID for carbon and ten times more sensitive than the FPD for sulfur. The utility of the AED for the analysis of pesticide residues has been described.\(^{103,104}\)

5.2 High-performance Liquid Chromatographic Separations

HPLC is a separation technique complementary to GC in that a large portion of the known organic compounds (about 90%), that for reasons of low volatility, high polarity and water solubility, or thermal instability are not amenable to GC analysis, can be separated by some form of HPLC technique. The separation is based on partition between a mobile liquid phase and an immiscible stationary phase. HPLC columns are typically stainless steel cylinders 1 to 4 mm internal diameter, 10 to 30 cm long, and packed with 1 to 10µm diameter beads of silica or other material that functions as the stationary phase. The most common mode of operation in HPLC is reversed-phase.

The most commonly used detectors for residue analyses are the UV/VIS absorption detector and the fluorescence

In recent years, there is a growing trend of the use of MS detectors. A summary of the principle of operation and examples of selected applications of these popular detectors is given in Table 4.

The UV/VIS detector is based on the absorption of ultraviolet and/or visible light by components of the sample as they pass through the flow-cell. Sensitive detection of components depends on high specific absorption of the compound at the operating wavelength and very low or zero absorption by the mobile phase. In contrast, the fluorescence detector gives excellent sensitivity and selectivity for target compound analyses of substances or derivatives which strongly fluoresce. Two other selective detectors which have been used for herbicide analysis include the radioc hemical detector (for radiolabeled analytes) and the photoconductivity detector.

In recent years, technology has developed such that interfaces and ionization techniques are now starting to meet the quite disparate requirements of the HPLC and the mass spectrometer. For example, the thermospray interface (TSP) is a popular, versatile, reliable and rugged interface suitable for routine use. Another popular MS source is the electrospray ionization (ESI) source. This interface is well suited to capillary columns and can produce very reproducible spectra of large or thermally labile compounds. The key concepts and techniques for MS detectors have been reviewed by Garcia and Barcelo.

5.3 Capillary Electrophoretic Separations

CE is a relatively new technique that provides high-speed separations of herbicide residues in extracts of environmental and biological matrices. Separations are carried out in fused silica capillaries, 25 to 75 µm internal diameter, about 50 cm long and filled with a buffer solution. A potential difference of 20 to 40 kV is applied between the ends of the capillary. The high electric field creates an electroosmotic flow of the buffer from the anode (positive) to the cathode (negative). Ionized organic molecules also migrate under the influence of the electric field and are separated according to differences in their electrophoretic mobility. Very specific separations of analytes can be accomplished by adjusting the pH, careful control of the nature of the buffer, the addition of organic solvents such as ACN, and the nature and concentration of surfactants. A variety of detectors are available for CE analyses, including UV/VIS, fluorescence, amperometric, conductivity, and MS detectors.

CE provides many advantages over traditional HPLC and GC separations. Peak widths are very narrow and resolution is high, resulting in very short analysis times. Very small injection volumes of less than 100 nL can be utilized. The operation of the instrument can be easily automated. CE separations have been demonstrated for the triazine herbicides prometryn [CAS 7287-19-6], terbutryn [CAS 886-50-0], desmetryn [CAS 1014-69-3], simazine [CAS 122-34-9] and atrazine [CAS 1912-24-9], the cationic herbicides paraquat [CAS 4685-14-7] and diquat [CAS 2764-72-9], and glyphosate [CAS 1071-83-6].

5.4 Immunochemical Methods

Immunoassay methods are based on the ability of antibodies to “recognize” and attach themselves to molecules with very great specificity. These methods have several advantages over conventional chromatographic methods. Analyses can be performed using crude extracts of tissues, reducing clean-up costs and preparation time. Once optimized, they can facilitate high sample throughput at relatively low cost compared to conventional approaches for screening of herbicide residues. Furthermore, the immunoassay kits are easily field portable.
The more popular methods are: the indirect enzyme-linked immunosorbent assay (indirect ELISA), direct ELISA, and radioimmunoassay (RIA). The details of these methods can be found in various reports.\textsuperscript{(113–115)} Immunosay systems have been developed for such herbicides as atrazine, terbutryn, chlorsulfuron \([\text{CAS } 64902-72-3]\), 2,4-D \([\text{CAS } 94-75-7]\), 2,4,5-T \([\text{CAS } 93-76-5]\), diuron \([\text{CAS } 330-54-1]\), linuron \([\text{CAS } 330-55-2]\), monolinuron \([\text{CAS } 1746-81-2]\), diclorop-methyl \([\text{CAS } 51338-27-3]\), paraquat, and picloram \([\text{CAS } 1918-02-1]\) in water samples.\textsuperscript{(113,114)} Detection limits are typically 0.08 to 5 \(\mu\text{g} \text{L}^{-1}\), and the methods are best used as a screening tool. While there has been much work done on detection of herbicide residues in soils and water,\textsuperscript{(114)} little work has been done for the direct determination of herbicides in biota. Methods have been described for the analysis of paraquat residues in milk, beef and potatoes\textsuperscript{(116)} and imazamethabenz \([\text{CAS } 100728-84-5]\) in cereal grain.\textsuperscript{(117)}

6 OFFICIAL MULTIRESIDUE METHODS FOR PESTICIDE RESIDUE ANALYSIS

Over the last 40 years a number of MRMs have been adopted by various government regulatory agencies to screen, quantify and confirm pesticide residues, including herbicides in foods and commodities.\textsuperscript{(26)} Since little is known, prior to analysis, about the nature and levels of possible contamination, MRMs have to be capable of determining a broad spectrum of analytes. The MRMs in common use are rugged, well-suited to handle large numbers of samples with relatively short turnaround times, and cost-effective, that is, the cost per analyte per sample is low. The most widely used official MRMs are based on the following methods: Mills,\textsuperscript{(118)} Mills, Onley, Gaither,\textsuperscript{(119)} Storbery,\textsuperscript{(120)} Luke,\textsuperscript{(75)} and Krause.\textsuperscript{(121)} United States agencies, such as the Food and Drug Administration (FDA) and the Department of Agriculture, use methods validated by the Association of Official Analytical Chemists (AOAC).\textsuperscript{(91)} European agencies commonly use the methods of Specht.\textsuperscript{(122,123)} Many of the MRMs in use have been reviewed by Motohashi et al.\textsuperscript{(27)}

The methods used by the US FDA Total Diet Program typify the MRMs in use for screening foods and commodities for pesticide residues.\textsuperscript{(124)} One procedure, AOAC method 970.52, is used to screen for organochlorine and organophosphorus pesticide residues.\textsuperscript{(96)} Samples of non-fatty foods are extracted with ACN or with aqueous ACN depending on water and sugar content. Fatty tissues are first extracted with diethyl ether then partitioned between light petroleum and ACN. The ACN phase containing the extracted residues is diluted with water and partitioned into light petroleum. The partitioned extracts are cleaned-up on a Florisil\textsuperscript{®} column. Additional clean-up, when necessary, is performed using a column of MgO (magnesia) and Celite\textsuperscript{®}. The residues are then determined by GC with various specific detectors. This ACN extraction-based method is based in part on methods developed by Mills and co-workers.\textsuperscript{(118,119)} The California Department of Food and Agriculture improved this method by using SPE columns to eliminate the use of DCM and reduce the number of labor-intensive LLP steps.\textsuperscript{(125)}

An alternative to the ACN-based method is AOAC method 885.22,\textsuperscript{(91)} which is based on the acetone extraction method of Luke.\textsuperscript{(75)} Nonfatty samples are blended with acetone and filtered. The filtrate is partitioned with light petroleum and DCM. The DCM is evaporated with additions of light petroleum followed by acetone to remove DCM and leave any pesticide residues dissolved in acetone. Pesticide residues in this acetone solution can be determined by GC without further clean-up. The absence of a chromatographic clean-up step permits the determination of many of the polar residues which are not recovered from Florisil\textsuperscript{®}, or charcoal–MgO–Celite\textsuperscript{®} clean-up columns.

The methods of Specht\textsuperscript{(122,123)} are the basis of the MRM DFG S19 adopted by Germany.\textsuperscript{(27)} Samples are extracted with aqueous acetone, the amount of water dependent upon the amount of moisture in the samples. After the addition of NaCl and partitioning with DCM, the extract is exchanged into cyclohexane–EtOAc and cleaned up using GPC. The fraction containing the residues is exchanged into EtOAc. Phosphorus-, nitrogen- and sulfur-containing residues are determined by GC with specific detectors. Organochlorine pesticide residues are determined by GC after further clean-up on a silica gel column.

The MRMs described above do not recover acidic herbicides such as chlorophenoxy acids and their chlorophenol transformation products. Such herbicide residues can be determined by a method described by Hopper\textsuperscript{(126)} and incorporated into the US FDA Pesticide Analytical Manual I as method 402.\textsuperscript{(127)} Acidic and phenolic residues are extracted with acidic DCM, MeOH or aqueous MeOH, depending on the commodity. Extracts are concentrated and residues exchanged into hexane prior to clean-up by GPC. Acids and phenols in the cleaned up extract are methylated using methyl iodide in the presence of tetra-butilammonium hydroxide, and further cleaned up using a miniature Florisil\textsuperscript{®} column. Methyl esters and ether derivatives of the acidic and phenolic residues are determined by GC with ECD or HECD operated in halogen or nitrogen modes.

A useful source of information on MRMs for determination of herbicide residues in foods and commodities is the US FDA Pesticide Analytical Manual, Part I, which is
available in its entirety in electronic format via the Internet from the US FDA Center for Food Safety and Applied Nutrition at the following site: http://vm.cfsan.fda.gov/.

1 INTRODUCTION

The development of chemicals in selective control of weed growth is a fascinating success story that has unfolded largely since the early 1980s. At present, herbicides represent the largest single agrochemical sector, worth approximately US$15 billion.

In order to limit environmental pollution and damage to humans, the main goals should be to produce herbicides that are more specific towards target plants, that can be applied in low doses, and that are rapidly degraded and inactivated by the environment. Until recently herbicide treatment was made following the pre-emergence (PrE) procedure, namely the herbicide was spread over the soil after sowing, but before crop germination.

Continuous research progress has produced herbicides that are so selective and efficacious that they may be applied at very low concentrations (down to 1 g ha\(^{-1}\) rather than the 500–2000 g ha\(^{-1}\) of traditional pesticides), directly on foliage, and only when the danger threshold is approached. Thus PrE treatments have been superseded by post-emergence (PoE) treatments in which herbicide application takes place after germination.

A PoE herbicide can be defined as a foliage-applied product used to control weeds that have emerged in competition with the developing crop. PoE herbicides’ high selectivity make it necessary to treat specific crops with specific compounds, (i.e. compounds that are well tolerated by the crop but not by the weeds), thus avoiding the more persistent and environmentally less safe PrE herbicides. However, many PoE herbicides retain residual activity in the soil and can thus control late-germinating weeds. The more used classes of PoE herbicides, which are predicted to become increasingly popular in the near future, are listed in Table 1.

The opportunity offered to farmers, to use small amounts of chemicals with a very low toxicity to mammals, has encouraged a fast worldwide diffusion of PoE herbicides as shown in Figure 1.

Even though the risk to humans of ingesting toxic doses of herbicide residues in food seems low, it is important to monitor herbicide levels in the environment and food commodities because of their extensive use and documented occurrence both in the environment and in foods. By “residues” is meant low levels of pesticides and their metabolites that remain in food after application.

To protect the health of their consumers, most countries...

CoA, coenzyme A.

have introduced laws not only governing the use of pesticides but also setting limits for the levels of pesticide residues that can be tolerated in drinking water and foods. The maximum residue limit (MRL) is the maximum acceptable level of a residue that regulatory authorities will tolerate on the basis of toxicological food intake data.

2 REGULATIONS

The “Maximum Admissible Concentration” of pesticides in drinking water is defined by the European Community Water Directive as 100 ng L\(^{-1}\) for individual pesticides and as 500 ng L\(^{-1}\) for the sum of pesticides.\(^{1(3)}\)

Pesticide residues in food are regulated at the international and national levels according to the toxicity of the pesticide and the human intake of a particular crop. The levels of pesticide residues are controlled by the MRLs, established by each country. These sometimes cause conflict because residue levels acceptable in one country can be unacceptable in another. This problem of MRL harmonization has been mainly dealt with by two international organizations: the European Union (EU) at European level, and the Codex Alimentarius Commission,\(^{2(3)}\) an international body established in 1962, to implement the Joint FAO/WHO Food Standards Program. Nations that are members of the Food and Agriculture Organization (FAO) and World Health Organization (WHO) may become members of the Codex Alimentarius Commission.\(^{4}\)

The EU directives promulgated between 1976 and 1989 achieved only partial harmonization because they fixed the MRLs of only 64 out of the more than 600 active ingredients on the market.\(^{5}\) In 1990, the EU issued a new directive that fixes MRLs for all EU countries, thus eliminating the higher MRLs acceptable in some countries.\(^{2(3)}\)

There are EU directives that establish sampling and analytical methods for the official control of pesticide

Figure 1 Herbicide diffusion in the world. (Source: United States Environmental Protection Agency (USEPA).)
residues in fruit, vegetables, and products for human consumption. Also, an EU directive published in 1991 covers the marketing of pesticide products. This demands a large number of studies on residues before an active ingredient can be authorized at European level.\(^5\)

In the USA, food safety is an important responsibility not only of the Food and Drug Administration (FDA), but also of the United States Department of Agriculture (USDA), the USEPA, and other agencies at the federal, state, and local levels. The USEPA registers or approves the use of pesticides and establishes a tolerance level if the use of a pesticide may lead to residues in food.\(^6\)

The FDA is responsible for enforcing the USEPA-established pesticide tolerances for foods shipped in interstate commerce, with the exception of meat and poultry, which are the responsibility of the USDA.\(^7\)

The detection and determination limits required for routine analytical methods for herbicide residues should not be higher than 10–50\% of the corresponding MRL as recommended by Frehse.\(^8\) This puts the highest requirements of methods for the determination of residues in drinking water, where the maximum permissible levels are sometimes as low as 100 ng L\(^{-1}\), and in food.

### 3 ANALYTICAL METHODS FOR DETERMINATION OF POST-EMERGENCE HERBICIDES IN ENVIRONMENTAL AND FOOD SAMPLES: GENERAL

In order to analyze PoE herbicides, knowledge of the physical and chemical properties of the classes of pesticides is essential to develop the best residue analytical methods with the most appropriate instruments.

The sequence of steps in the analysis are the sample preparation and determination. The sample preparation consists in the extraction and cleanup procedures.

#### 3.1 Extraction

The extraction of PoE residues from the matrix is a requisite for almost all the methods of analysis, either for the whole body of water sample or for solid or semisolid substances. A wide variety of extraction procedures have been used to remove PoE residues from environmental water, soil, and food.

For liquid samples, extraction will be accomplished by liquid–liquid extraction (LLE) partition using an organic solvent nonmiscible with water, by solid-phase extraction (SPE), or solid-phase microextraction (SPME) techniques, and supercritical fluid extraction (SFE) after enrichment on a precolumn packed with a polymeric phase.

Extraction of a solid or semisolid sample depends on the polarity of the PoE residues as well as the polar matrix. If the PoE residues are ionic or polar compounds, samples are usually extracted by mixing with pH-adjusted water or organic solvent diluted with pH-adjusted water using a shaker, blender, Polytron\textsuperscript{™}, sonication, or Soxhlet. For less polar PoE residues, organic solvents (acetonitrile, methanol, acetone, ethyl acetate) and solvent mixtures are ground with the samples. The extraction solvents and residual solids are then separated by filtration or centrifugation.

Newer techniques for the extraction of PoE residues are:

- SFE using a supercritical fluid, usually carbon dioxide, with or without organic modifier (methanol, acetonitrile);
- microwave-assisted extraction (MAE), which has the advantages of lower solvent consumption and greater speed than conventional extraction;
- soil column extraction (SCE), using organic solvent mixed with pH-adjusted water. This technique reduces the complexity of the analytical method and the sample preparation time.

#### 3.2 Cleanup Procedures

An extraction technique is selected to obtain the highest recovery for a wide range of contaminants. Therefore, the extract is likely to contain a high proportion of coextracted material. The goal of cleanup is to remove as much interfering coextractive material and as little of the analyte as possible. A cleanup procedure for sample extracts is often required, depending on the type of compound and kind of sample to be analyzed and for the selectivity of the analytical equipment used in determination.

Liquid–liquid partition (LLP) is the most common first step in cleaning up the extract to remove water-miscible solvents or reduce the amount of fat present in the extracts. The extraction efficiency can be enhanced by adding sodium chloride or sodium sulfate to salt out the analyte. If the PoE analyte is an acid, it can be brought into the aqueous or organic phase by modulating the pH value.

The cleanup techniques most commonly employed for extracts containing PoE residues are column chromatographic SPE systems and gel permeation chromatography (GPC).

Open-column chromatography uses columns packed with florisil, silica or alumina in the normal phase, or with reversed-phase (RP) columns of C\(_{18}\), cyanopropyl, phenyl
or graphitized carbon black (GCB). These columns can be prepared in the laboratory, or use can be made of SPE cartridges.

To some extent, interference can be overcome by using size-exclusion chromatography (SEC) with gel, for example, GPC. The most useful gel for PoE cleanup is BioBead SX-3. A disadvantage of the GPC step is that it is slow and requires the use of comparatively large volumes of solvent with the attendant risk of contamination.

3.3 Determination

Nowadays the classic techniques for determination and quantification of PoE residues in environmental and food samples are GC and HPLC. GC and HPLC, in conjunction with mass spectrometry (MS), can be powerful tools for confirmatory analysis. IAs are now being seen as useful supplements to classical chromatographic analytical systems. IA provides a specific reaction with a compound or a group of compounds, which could reduce matrix effect and the need for sample cleanup and concentration. Classical direct current (DC) polarography and fast scan differential pulse voltammetry (FSDVP) have also been applied.

3.3.1 Gas Chromatography

GC on a packed column or capillary column is still the most common separatory technique in PoE residue analysis, and the most common detection systems are nitrogen–phosphorus detection (NPD), electron capture detection (ECD), atomic emission detection (AED), and flame ionization detection (FID). The direct analysis of PoE acids by GC is obstructed because of their acidic character and low volatility. Therefore, derivatization is usually necessary before GC analysis. In environmental applications, the most-used derivatization procedures employ diazomethane, 2,2,2-trifluoroethanol (TFE), pentafluorobenzyl bromide, methyl, ethyl and butyl chloroformate, and trifluoroethyl bromine.

3.3.2 High-performance Liquid Chromatography

Nowadays, HPLC is being extensively used in PoE residue analysis and related areas where the chemicals of interest are frequently of low volatility for GC separation. Briefly, HPLC methods for determination of the PoE residue in environmental samples could employ RP chromatography with C_{18}, C_{8}, cyanopropyl, and phenyl columns followed by ultraviolet (UV) absorption, UV diode array detector (DAD), fluorimetric (FI) detection, amperometric electrochemical detection (AD) and photoconductivity detection (PCD). Isocratic or gradient elution with a large change in mobile-phase composition is also used. Buffer solutions with the pH adjusted below the pK_a values of the acidic compounds are commonly employed. For ionic PoE residues an ion-pairing mechanism has been reported.\(^9\)

3.3.3 Hyphenated Techniques

The confirmation of all results is a fundamental requirement of PoE residue analysis, as in all other trace analyses. As chromatography is a poor identification technique, hyphenated techniques have been developed and have gained popularity for increasing the selectivity and the certainty of identification.

MS, coupled with GC or HPLC, is being used more often.

3.3.4 Immunoassays

Although IAs have been widely used in clinical analysis since the 1960s, their application in pesticide residue determination is recent. At the present time, PoE residual determination has only been developed for IMIs and for diclofop-methyl. Application of IAs in PoE analysis will probably increase in future. This technique has great potential because it offers many advantages including sensitivity, specificity, and analysis speed.

However, the disadvantage is that each kit is specific to a single analyte.

3.3.5 Other Techniques

Nitropesticides have been studied with the aim of establishing their electrochemical reduction and adsorption characteristics at the mercury-drop electrode with regard to the medium acidity and the compound structure.

4 IMIDAZOLINONE HERBICIDES

4.1 Chemical and Physical Properties

The chemical structures, names, and chemical abstracts service registry numbers of IMI herbicides are reported in Table 2. The basic physical, chemical, and other properties of the IMI herbicides are listed in Tables 3–5. The data in these tables are taken from *The Pesticide Manual*.\(^{10}\)

The IMIs are a relatively new class of herbicides, used to control a wide spectrum of broad-leaved weeds and grasses in a variety of agricultural commodities.\(^{8,11}\) These herbicides are very potent weedkillers and are used in doses that are substantially lower than conventional herbicides.

The water solubility and vapor pressure of the IMI carboxylic acids are low, whereas the octanol–water

Partition coefficients are pH dependent. At pH 4, the IMI carboxylic acids are neutral and therefore lipophilic, whereas at pH 7 the carboxylic acids are ionized. The pK\(_a\) values of several IMI herbicides lie between 1.9 and 11.4. Up to three inflection points have been observed in the titration of IMIs. The IMI ring is amphoteric and behaves as a weak base or a weak acid. The first inflection point corresponds to protonation of the IMI ring at pK\(_1\) of about 1.9–3.3, whereas the second reflects ionization of the carboxylic acid at pK\(_2\) values around 3.6–3.9. The third inflection point, determined only for imazapyr, corresponds to IMI ring deprotonation at a pK\(_3\) of about 11.4.

The hydrolytic stability of the IMI ring is pH dependent. At environmentally relevant pH and temperature, hydrolysis is very slow. At pH less than 7, the IMI ring is stable.

As shown in Table 2, the members of this class of herbicides have similar structural features centered around the IMI ring and an attached aromatic system bearing a carboxylic acid moiety. IMIs have an excellent activity against annual and perennial grasses and broad-leaved...

weeds when applied either PrE or PoE. They function by inhibiting acetohydroxy acid synthase (AHAS), the feedback enzyme in the biosynthesis of branched-chain essential acids. This enzyme is not present in animals.

In order for a herbicide to kill plants, the chemical must be adsorbed and translocated to the site of action. In the case of IMIs, the site of action is the AHAS enzyme, which is concentrated in plant meristematic tissues. IMIs enter plants through the root or shoot tissue and are then translocated throughout the plant via the xylem, the water transport system, or the phloem, the sugar transport system. The mechanism by which IMIs are adsorbed and retained within plant cells is called

Fate in:
- **animals**: rapidly excreted
- **plants**: methyl group of benzene moiety is oxidized to hydroxymethyl

**Uses**
- U1 = PoE control of Avena spp., Alopecurus myosuroides, Apera spica-venti and some dicotyledonous weeds in wheat, barley, rye, and sunflowers;
- U2 = PoE weed control in soybeans, and other legumes grown in rotation with sugar beet and other crops where more persistent IMIs are not suited;
- U3 = PoE control of annual and perennial grasses, sedges and broad-leaved weeds, as well as many brush and deciduous tree species;
- U4 = PrE and PoE control of broad-leaved weeds in soybeans;
- U5 = PrE and PoE control of annual and perennial grasses and broad-leaved weeds in soybeans and other leguminous crops.

Ion-trapping. The pH gradient that occurs within plants is typically pH 4.5–5 outside the cell and 7–7.5 inside the cell. Although IMIs are water-soluble compounds, under acidic conditions the molecules are relatively more lipophilic and, as such, are able to diffuse across cell membranes. Once inside, the molecule becomes charged in the alkaline environment with a concomitant decrease in lipophilicity. Because the charged form of the IMI is slower to diffuse across the plasma membrane, the compound accumulates, or is trapped within the cell.

Imazapyr is a broad-spectrum herbicide that controls most annual and perennial grasses and broad-leaved weeds, woody brush, and deciduous trees in noncrop areas such as railroads, utility areas, pipeline and highway rights-of-way, utility plant sites, petroleum tank farms, pumping installations, fence rows, storage areas, and nonirrigation ditches. It is used to establish and maintain wildlife openings, to prepare sites for conifer planting, and to release conifers from competing vegetation. Imazapyr has also been developed for use in sugar cane and plantation crops, such as rubber and oil palm.

Imazapyr PoE application is preferred in most situations, particularly for the control of perennial weeds. For maximum herbicidal activity, imazapyr should be applied when the weeds are growing vigorously.

Imazaquin was the first IMI to be widely accepted as a herbicide for broad-spectrum weed control. Initial results have demonstrated that imazaquin can be applied preplant incorporated, PrE, or PoE for the control of many difficult-to-control soybean weed species.

In early testing, it was discovered that imazaquin applied as a PoE treatment uniquely provided both burndown of susceptible weeds present and residual control of later-germinating weeds.

Imazethapyr is a selective IMI used to control a wide spectrum of broad-leaved weeds and grasses in soybeans and several leguminous crops. Imazethapyr is a uniquely flexible herbicide that can be applied early preplant, at planting, or PoE. The herbicide is very effective in no-till as well as conventional tillage situations. Residual season-long control was recognized as an important feature of imazethapyr, and in general it was determined that optimum application rates for soil and PoE applications are the same, and efficiency is not affected by soil type or characteristics.

Imazamethabenz-methyl is a selective, PoE herbicide used to control weeds in cereal crops. It controls many of the economically important weeds that infest wheat, barley, and rye. Imazamethabenz-methyl is applied as ester, but it is the acidic form that is herbicidally active.

The first sign of herbicidal activity is chlorosis of the youngest leaves; later in the season the whole plant becomes necrotic or remains as a small, noncompetitive weed at the base of the crop.
Imazamethabenz-methyl also has soil residual activity; thus, susceptible weeds that germinate after application can be controlled.

The IMI herbicides have been subjected to exhaustive toxicological studies to determine their toxicity to mammals and other nontarget organisms and to evaluate the potential hazard of handling and applying these herbicides. As demonstrated by the results of those studies, the IMIs have a low toxicological potential, partially because they act by inhibiting a biosynthetic process at a site present only in plants. In addition, these herbicides are excreted rapidly by rats before they can accumulate in the tissues or blood.

4.2 Analytical Methods for Imidazolinone Analysis

4.2.1 Extraction

The extractive solvent and the method used depend on the nature of sample. For liquid samples, particularly for groundwater and surface water, extraction has been obtained by using a 6-mL SPE column packed with 1 g of Baker Light-load Octadecil or Waters Sep-Pak Plus Environmental. Extraction from solid samples depends on the polarity of the pesticides as well as the sample matrix. For food samples, extractions are usually performed by mixing them with methanol or a methanol–water (25:75) solution acidified with HCl. For solid samples such as environmental soils, extraction can be carried out in two ways: (1) mechanically stirring the sample with different organic solvents, such as methanol, acetone, ethyl acetate, diethyl ether, 2-propanol, ethanol, and dichloromethane, and (2) extracting imazamethabenz-methyl and imazaquin by SFE, usually using CO2 with methanol as organic modifier. Two new techniques that have been developed to extract IMIs from solid samples are MAE and SCE. Stout et al. found that MAE with NH2OAc/NH4OH (0.1 mol L\(^{-1}\), pH 10) as the extractant achieved the best results with different soils. They applied the same technique, using several types of extractants: (namely H2O, CH3OH, 10% H2O/CH3OH, and 0.1 mol L\(^{-1}\) NH2OAc/H2O) to the extraction of imazethapyr, its hydroxide metabolite, and the glucose conjugate from 11 different preparations. m-imazamethabenz, p-imazamethabenz, m-p-imazamethabenz-methyl, imazapyr, imazaquin and imazethapyr have been extracted by SCE, using as the extraction phase a methanol–ammonium carbonate mixture (0.1 mol L\(^{-1}\), pH 8.2, 50:50, v/v). The SCE technique makes the sample preparation method efficient and economical, and the preparation time is reduced.

4.2.2 Cleanup

The extract obtained during an extraction step usually has to undergo a further cleanup procedure. After solid samples have been ground in the presence of a mixture of polar solvent and water-immiscible solvent, the resulting mixture is cleaned up by LLP and/or column chromatography.

The solvent partition system used in IMI residue analysis includes dichloromethane, hexane, and hexane–EtOAc (1:1). For the solvent partition system of oil obtained after the filtrate evaporation under reduced pressure, Mortimer and Weber used 1 N NaOH and 25 mL of hexane–EtOAc (1:1). The aqueous layer was removed, and the organic layer was extracted with an additional 10 mL of 1 N NaOH. The combined aqueous layers were first back-extracted with 15 mL of hexane–EtOAc (1:1), acidified to pH 3 with 10 N H2SO4, and extracted with two 20-mL portions of dichloromethane. Currently SPE is predominant in the cleanup of IMI residues. One or more SPE columns packed with various types of sorbents have been developed and applied. The nonpolar material octadeyl (C\(_{18}\)) is the most commonly used sorbent in IMI analysis. A better cleanup C\(_{18}\) sorbent is used in tandem with an SCX cartridge and an SAX cartridge. Curran et al. use solid-phase octyl (C\(_{8}\)) and aromatic sulfonic acid cartridges for imazaquin cleanup from soil. A sorbent of diol-bounded silica in a single column has also been used for the cleanup of imazethapyr in soybeans. A GCB, Carbograph-1, has been evaluated as a cleanup system in the soil analysis of six main IMIs.

4.3 Determination

All of the analytical methods for IMI residues are based on chromatography, mainly GC and HPLC, hyphenated and immunochemical techniques (see Tables 7–10).

4.3.1 Gas Chromatography

Two gas chromatographic methods have been developed for the determination of imazethapyr in soybeans and soil. Both make use of a capillary column with a bonded phase of low polarity (DB-5) and NPD to determine the residue. For GC analysis, the method exploits the ready cyclization of the nonvolatile acid imazethapyr to the volatile imidazoisindol-3,5-dione using an excess of dimethylaminopropylethylcarbodiimide hydrochloride.

Table 7 shows examples of IMI determination by GC, and Figure 2 presents the chromatograms of imazethapyr in soybeans analyzed by GC/NPD.

4.3.2 High-performance Liquid Chromatography

HPLC is being extensively used in IMI analysis. The advantage of HPLC over GC is that the quantification of acidic IMI is carried out without need of derivatization.

The diverse methods used to determine IMI in environmental samples are shown in Table 8. Summarizing them, HPLC methods for the determination of residues employ RP chromatography with C₁₈, C₁₈, or C₈ columns. For increasing the selectivity in the analysis of imazapyr and imazethapyr from soil, Nováková employs a column-switching method using two separation columns. Whether in isocratic or gradient mode, all mobile phases are formed from aqueous solutions acidified with different acids: formic, phosphoric, and acetic. UV detection, usually operated in the range 235–260 nm, is the only detection method utilized in the analysis of IMI residues. Table 8 summarizes representative papers using this technique. HPLC/UV chromatograms obtained by analyzing groundwater, lake, and river water spiked with six IMI herbicides are shown in Figure 3.

4.3.3 Hyphenated Techniques

The successful combination of MS with GC and subsequently with liquid chromatography (LC) has enabled not only the determination of IMI pesticides but also the identification of their residues at trace levels. The three modes of GC/MS that have been used are electron impact (EI), positive chemical ionization (PCI), and negative chemical ionization (NCI). GC/MS in EI mode using selected ion monitoring (SIM) is used in the determination imazethapyr in soybeans, imazamethabenz-methyl in soil, and imazapyr in corn. PCI and NCI are good alternative ionization methods which offer better selectivity and/or sensitivity than EI. In the work proposed by Stout et al., the authors demonstrate that analyte detecting with the sensitivity and specificity of GC/ECNCI/MS reduces the required cleanup. Stout
et al.\(^{(21)}\) wanted to evaluate the potential utility of GC with EI/MS on a less expensive GC/ECNCI/MS for the determination of imazapyr in corn.

HPLC coupled with MS provides the analyst with a powerful tool for IMI residue determination. Interfacing these devices is most commonly done by employing a particle beam (PB) or electrospray ionization (ESI) technique. HPLC/PB/MS has been applied for confirming imazamethabenz-methyl\(^{(22)}\) in soil. By combining LC with electrospray ionization/mass spectrometry (ESIMS) or electrospray ionization tandem mass spectrometry (ESIMS/MS)\(^{(31)}\) IMIs present in water can be monitored simultaneously at the 1 ppb level with only a simple filtration prior to analysis. The same authors developed a method for the rapid and direct determination of imazethapyr and imazamethapyr in soil by using LC/ESIMS and LC/ESIMS/MS;\(^{(28)}\) an analytical procedure based on LC/ESIMS\(^{(30)}\) is employed for targeted imazethapyr and its metabolites in a wide range of crop commodities. LC/ESIMS is a selective approach particularly suitable for confirming the presence of imazapyr, \(m\)-imazamethabenz, \(p\)-imazamethabenz, \(m\text{-,}p\)-imazamethabenz-methyl, imazethapyr, and imazaquin in two types of samples:\(^{(18)}\) (1) for groundwater, lake water, and river water samples the analysis is made by HPLC/ESIMS in full-scan mode; (2) for soil samples LC/ESIMS under three ion SIM conditions is employed.

Table 9 shows examples of IMI herbicides determined by these hyphenated techniques and Figure 4 depicts chromatograms from LC/ESIMS of an unfortified, and a fortified soil with imazethapyr at the 1 ppb level.

### 4.3.4 Immunoassay

IAs are now being seen as useful supplements to classical chromatographic analytical systems. The near future will also see an integration of immunochemical and classical procedures.

IA provides rapid, sensitive, and cost-effective analysis for a variety of IMI residues. The main disadvantage is that only one compound at a time can be determined. The usefulness of these techniques is experienced during screening analysis when a large number of samples have to be analyzed in parallel for a simple analyte within a short time. Among the different IA procedures for determining the IMI residue, the most explored is enzyme-linked immuno-adsorbent assay (ELISA).
ELISA is applied to the analysis of surface runoff water and to the analysis of more complex matrices such as agrochemicals and cereal grain. In the analysis of imazaquin and imazamethabenz, erroneous results could be produced by matrix effects or the inability to differentiate between structurally similar compounds (cross-reactivity).

For tap and groundwater, Lee and Durst have developed an assay based on sequential competitive binding of imazethapyr and liposomes for a limited number of antibody binding sites. A capillary tube with immobilized antibody was used as the immunoreactor column. Liposomes that entrap fluorescent molecules as the detectable label provide instantaneous, rather than time-dependent, enhancement, common with enzyme IAs. Bioassay techniques are applied for the determination of imazaquin and imazethapyr in soil. In the method proposed by O'Bryan et al, three corn-root bioassays were evaluated for detecting imazaquin in soil. Two techniques, one which utilized a cone-shaped tube as a growth container and another a petri dish, were compared to a method that utilized a thin layer of soil between two 20 cm glass plates. Representative examples are summarized in Table 10.

Figure 4 Chromatograms from LC/ESIMS of (a) blind Indiana soil with apparent imazethapyr at 0.17 ppb and (b) Indiana soil fortified with imazethapyr at 1 ppb. (Reprinted from The Journal of AOAC International, 80, 426–432 (1997). Copyright, 1997, by AOAC International.)
5 ARYLOXYPHENOXYPROPIONIC ACIDS/ESTERS

5.1 Chemical and Physical Properties

Since the late 1980s, many heterocyclic oxyphenoxypropionic acid derivatives have been prepared as a new class of selective herbicides for the control of graminaceous weeds in broad-leaved crops and tolerant cereals. Esters of aryloxyphenoxypropionic acids are a new series of highly selective PoE herbicides, often termed “phenoxynoxys”. In the treated plants they decompose fairly rapidly, yielding the corresponding free acids as the main metabolites.

The chemical structures, names, and chemical abstracts registry numbers of aryloxyphenoxypropionate (ArPP) herbicides are shown in Table 11. Tables 12–14 enumerate the chemical, physical, and other properties of ArPP herbicides.

Considerable progress has been made towards understanding the mode of action of the ArPP herbicides. Earlier studies suggested that these compounds disabled de novo fatty acid biosynthesis, but no specific site of action was identified. Recently, it has been demonstrated that they specifically inhibit acetyl-CoA carboxylase in susceptible plants. This enzyme catalyzes the adenosine triphosphate (ATP)-dependent formation of malonyl-CoA from acetyl-CoA and bicarbonate, that is the first committed step for fatty acid synthesis de novo.

In spite of their different structures they show the same symptomatology and selectivity of herbicidal action. In fact, they are PoE herbicides that are used for the control of annual and perennial grasses in a large variety of broad-leaved crop plants.

ArPP esters form colorless crystals or odorless solids, except for fluazifop-butyl which is a pale straw-colored liquid. This class of compounds is relatively stable in acidic media (pH 3), and in some cases in neutral conditions, undergoing slow hydrolysis to the free acid between 30 and more than 1000 days. This process is much faster in alkaline media (pH 9), ranging from 2.2 to 60 h. The \( pK_a \) values of the free acids are between 2.9 and 3.4.

ArPPs are selective herbicides with a systemic action. They are absorbed principally by the leaves, and in some cases by the roots, to undergo rapid transformation into the acidic form which is then translocated throughout the plant via the xylem or phloem system, accumulating in the meristematic tissues. All these compounds can be regarded as heterocyclic homologs of the wild oat herbicide diclofop, in which the terminal dichlorophenyl ring is replaced by a heterocycle, such as pyridine, quinoline, quinoxaline, benzothiazole, or benoxazole. ArPPs possess a chiral center and exist as a mixture of two optical isomers. The \( (R) \) enantiomer of fluazifop-butyl was the second case of a herbicide in which the introduction of the resolved form largely replaced the racemate. Although biological activity resides exclusively with the \( (R) \) enantiomer in PoE applications, the \( (R) \) and \( (S) \) enantiomers show equivalent activity when applied in PrE. This has been shown to be due to microbial conversion of the \( (S) \) to the \( (R) \) enantiomer in the soil.

The main uses are on soybeans, sugar beet, and cotton. Particular uses include control of volunteer cereals and other grass weeds in wheat, barley, rye, legumes, oil seed rape, sunflowers, fodder beet, flax, alfalfa, peanuts, beetroot, lettuce, spinach, potatoes, cucumber, peas, tomatoes, fennel, and strawberries.

With so many products already on the market or becoming available for the same use on the same crops in a relatively short period of time, severe competition is inevitable. Some efforts have been made to search for new applications.

Thus fenoxaprop-ethyl is only marginally selective in wheat, but addition of the safener fenchlorazole-ethyl has allowed the use of the herbicide on all wheat varieties except durum wheat. Racemic fenoxaprop-ethyl is formulated with the safener in a 4:1 ratio, whereas the active \( (R) \) isomer utilizes a 2:1 ratio. The safener does not influence either foliar uptake of the herbicide by wheat plants, or the degree of inhibition of acetyl-CoA carboxylase. However, levels of fenoxaprop-ethyl and of its herbicidally active free acid in shoot tissues of wheat decrease more rapidly when applied with fenoxaprop-ethyl; at the same time the formation of inactive metabolites of the herbicide increases.

The ArPPs have undergone many tests to determine their toxicity to mammals in order to prevent serious hazard to farmers. Test conducted on rats have shown that in most cases the ArPP is metabolized into the free acid and then excreted within 3–7 days in urine and feces. The toxicity class according to WHO is III for all compounds except for haloxyp, which is II.

5.2 Analytical Methods for Aryloxyphenoxypropionate Analysis

5.2.1 Extraction

Table 15 summarizes extraction and cleanup procedures used in the determination of ArPP herbicides.

Currently SPE is predominant in analytical methods used for ArPP herbicidal residues in water matrices. Conventional LLE with dichloromethane has been used in the monitoring of diclofop and haloxyp, and diclofop-methyl in groundwater.

Different SPE methods have been developed using C_{18} bonded-silica cartridges.\(^{39–45}\) On-line trace enrichment for diclofop-methyl and fluazifop-butyl screening in river water is obtained with a cartridge packed with a polymeric RP material.\(^{46}\) For the extraction of fenoxaprop in groundwater, Dupas et al.\(^{47}\) suggest an on-line device that utilizes a precolumn packed with the apolar PLRP-S. The same material is used by Wuchner and Grob.\(^{48}\) In such work, SFE is employed for the elution of diclofop-methyl, after enrichment on a precolumn packed with a polymeric phase. For the simultaneous extraction of clodinafop, diclofop, fenoxaprop, fluazifop, haloxyfop and quizalofop from drinking, spring, and groundwater, Laganà et al.\(^{49}\) employ three different SPE systems:

- a disposable SPE cartridge packed with Carbograph-1;
- a LiChrolut-EN cartridge, an ethylvinylbenzene–divinylbenzene (DVB) resin;
- an SPE disk, made of polystyrene–divinylbenzene (PSDVB).

Chromatograms obtained by analyzing 1 L of a groundwater sample spiked with six ArPPs, using two different SPE systems, are reported in Figure 5.

For solid samples, extraction with a water-miscible solvent is necessary. When the analyzed sample is food, the subsample can be homogenized with acetone,\(^{50–53}\) acetone–ethanol–2 mol L^{-1} HCl (2:1:1, by vol),\(^{54}\) 0.1 mol L^{-1} NaOH,\(^{55}\) 0.2 mol L^{-1} NaOH in methanol,\(^{56}\)

\(^a\) PRP-1, polymeric RP material; PLRP-S, copolymer styrene divinylbenzene.

Water, is adsorbed on the surface of activated florisil to obtain a free-flowing powder, which is extracted in a glass column with ethyl acetate or dichloromethane–acetone (90:10, v/v). The method proposed by Laganè et al.,\(^{60}\) for sample preparation involves a simple treatment of the soil sample via isolation and trace enrichment of fluazifop, haloxyfop, and diclofop by SCE.

Several methods have been proposed for the extraction of ArPPs from soil samples. These methods are as follows: Soxhlet with acetone;\(^{5,61}\) sonication with water and methanol;\(^{62}\) acetonitrile–light petroleum (50:50, v/v);\(^{57}\) 4 mol L\(^{-1}\) HCl and acetonitrile–light petroleum (2:1) (10:60, v/v);\(^{57}\) water and acetone or 6 mol L\(^{-1}\) HCl and acetone;\(^{63}\) and batch extraction with acetonitrile–water–acetic acid (80:19:1, v/v) followed by re-extraction by sonication with 0.1 mol L\(^{-1}\) KOH;\(^{64}\) mechanical shaker with 0.1 mol L\(^{-1}\) NaOH;\(^{55}\) 0.1 mol L\(^{-1}\) HCl–methanol (50:50, v/v) and ethyl acetate;\(^{65}\) dichloromethane and then 0.1 mol L\(^{-1}\) NaOH–methanol (50:50, v/v).\(^{66}\)

### 5.2.2 Cleanup

In the majority of instances, the initial extract contains a too high level of coextracted interfering compounds to allow direct analysis, and some form of cleanup is required.

In the LLP step, the extraction efficiency can be enhanced by adding sodium chloride to salt out the analytes\(^{50,52–55,61}\) or sodium sulfate.\(^{57}\) Dichloromethane is most commonly used in LLP\(^{52,55,56,65}\) Solvent mixtures such as petroleum ether and dichloromethane;\(^{51}\) hexane–diethyl ether (50:50, v/v);\(^{54}\) and chloroform and light petroleum\(^{57,63}\) are also used. For ArPP analysis, the most commonly used cleanup techniques are SPE packed with Florisil, alumina, silica gel, GCB, phenyl and cyanopropyl bonded phases, SPE-disk and size exclusion (gel permeation).

An alternative sorbent that is especially effective for cleanup of acidic ArPP herbicides is Carbograph-1;\(^{49,60}\) composed of nonporous spherical graphite particles. The advantage of using the Carbograph-1 cartridge was that extraction, concentration, and fractionation into classes were possible simultaneously (the acid analytes were separated from the neutral to basic ones by differential elution). The presence of some active centers bearing a positive charge enables Carbograph-1 to behave as both a nonspecific and an anion-exchange sorbent. It follows that anionic ArPP herbicides were specifically adsorbed
Figure 5 HPLC/DAD chromatograms obtained by analyzing 1 L of a groundwater sample spiked with ArPP at the individual level of 100–200 ng L\(^{-1}\) by different procedures involving the use of (a) the LiChrolut-EN extraction cartridge and (b) the Carbograph-1 cartridge. Peaks: 1 = fluazifop; 2 = clodinafop; 3 = quizalofop; 4 = fenoxaprop; 5 = haloxyfop; 6 = diclofop. (Reprinted from *J. Chromatogr.*, 796, A. Laganà, G. Fago, A. Marino, 'Determination of Aryloxyphenoxypropionic Acid Herbicides in Water Using Different SPE Procedures and LC/DAD’, 309–318, Copyright 1998, with permission from Elsevier Science.)

on the Carbograph-1 surface via electrostatic forces and that they could be desorbed simply by adding a displacing agent (such as formic acid) to the organic solution. Carbograph-1 behaves like conventional exchangers if the stepwise elution of acidic compounds can be achieved on the basis of the acid strands, by appropriate selection of the displacing agents.

Open-column chromatography using a column packed with Florisil is used to remove the chromatographic interference in the determination of fluazifop-butyl and fluazifop in potatoes, soybeans, and soil samples.\(^\text{(55)}\) The six principal ArPP herbicides in fruit and vegetable samples are subjected to activated silica gel column cleanup.\(^\text{(54)}\) Silica gel is also used for cleanup of fluazifop-butyl and fluazifop in soil.\(^\text{(66)}\) Fenoxaprop and fenoxaprop-ethyl in different soils are purified on a Florisil or alumina cartridge.\(^\text{(65)}\) Diclofop-methyl and its metabolite diclofop were extracted and derivatized, and then the products were purified on a chromatographic column containing alumina, silver–alumina, and Florisil.\(^\text{(57)}\) The bromo derivative of fluazifop-butyl and the pentafluorobenzyl derivative of fluazifop are purified on a chromatographic column containing alumina and Florisil.\(^\text{(63)}\)

A C\(_{18}\) extraction disk, used in off-line mode, has been evaluated by Bao et al.\(^\text{(62)}\) for the cleanup of diclofop-methyl. Higher flow rates can be applied with an SPE disk and the extraction time is much shorter.

The large difference in polarities between fluazifop-butyl and fluazifop causes difficulties in the application of the sorbent extraction technology for the simultaneous determination of both compounds from soil extracts. Therefore, in the handling of soil extracts containing fluazifop-butyl and fluazifop, Zanco et al.\(^\text{(9)}\) have developed a combination of a phenyl phase and cyanopropyl-phase cartridges for the cleanup operation.

A method used for the cleanup of ArPP in complex matrices is GPC. It has been used for cleanup in the analysis of diclofop-methyl, fenoxaprop, haloxyfop-ethoxyethyl, quizalofop-ethyl,\(^\text{(50)}\) diclofop-methyl,\(^\text{(52)}\) fluazifop, and fluazifop-butyl.\(^\text{(61)}\) Separation is performed using Bio Beads SX-3, a polystyrene type gel, using solvents such as a mixture of cyclohexane and ethyl acetate (50:50, v/v),\(^\text{(52)}\) or cyclohexane and acetone (50:50, v/v).\(^\text{(53)}\) A liquid chromatographic step on silica gel was therefore inserted between the GPC and the GC step to filter out polar products.\(^\text{(52)}\) Figure 6 shows a typical GC/ECD chromatogram of a fruit sample.
extract containing haloxyfop-ethoxyethyl, fenoxaprop, and quizalofop-ethyl, cleaned up by gel permeation.

5.3 Determination

Chromatographic methods are most widely used for analytical separation, identification, and quantification of ArPP residues in different matrices.

5.3.1 Gas Chromatography

Table 16 summarizes the column, detector, and DL currently employed in routine GC ArPP residue analysis, and Figure 7 shows chromatograms of diclofop-methyl residues in soil and crops. Capillary GC in combination with selective detectors, mainly ECD and NPD, are the most common techniques for ArPP determination. The use of other detectors, such as FID and AED, have been reported in only one case. The GC/AED is one type of spectrochemical method, and the incorporation of a microwave-induced plasma generator and a photodiode array has demonstrated its accuracy, reproducibility and simplicity.

Figure 6 GC/ECD chromatogram of melon extract fortified with haloxyfop-ethoxyethyl (0.33 mg kg\(^{-1}\)), fenoxaprop (0.28 mg kg\(^{-1}\)), and quizalofop-ethyl (0.29 mg kg\(^{-1}\)). (Reproduced from J. Chromatogr. A, 782, A. Gelsomino, B. Petrovicovă, S. Tiburtini, E. Magnani, M. Felici, ‘Multiresidue Analysis of Pesticides in Fruit and Vegetables by GPC Followed by GC with Electron Capture and Mass Spectrometric Detection’, 105–122, Copyright 1997, with permission of Elsevier Science.)

The data on the elemental composition of pesticides available from AED chromatograms makes the information content much higher than that obtained from conventional GC detectors. Several stationary bonded phases have been used in the determination of ArPP in different samples, including different polarities: SE-54, HP-1, DB-5, HP-5, and SE-52 are nonpolar, and 65% dimethyl–35% diphenylpolysiloxane and DB-1701 are polar.

The acidic ArPPs in the extract were derivatized with TFE, pentafluorobenzyl bromide, methyl, ethyl, and butyl chloroformate, diazomethane and bromine.

Figure 8 is a chromatogram of a groundwater sample spiked with fluazifop and haloxyfop, derivatized to their methyl esters.

5.3.2 High-performance Liquid Chromatography

HPLC is used extensively in ArPP residue determination. HPLC methods employ RP chromatography with \(C_{18}\) or \(C_8\) columns. For the determination of fluazifop the authors utilize a phenyl-bonded phase and cyano-bonded phase column.

APCI/NI, atmospheric pressure chemical ionization with negative ion mode of operation; IT, ion-trap.

Identification, a characteristic of chromatographic methods, cannot be solved with the application of a UV detector. An increase of confirmation ability has been achieved with the DAD. This technique has been used in the simultaneous HPLC analysis of clodinafop, quizalofop, diclofop-methyl, fluazifop-butyl, and fenoxaprop in aqueous samples. In the determination of fluazifop in soybean oil by HPLC, AD in oxidation mode is used to achieve selectivity and sensitivity.

Table 17 summarizes the column, mobile phase, detector, and DLs currently employed in routine ArPP residue analyses.

#### 5.3.3 Hyphenated Techniques

The identification and confirmation of analytical results is been obtained by combining MS with GC (GC/MS) or subsequently with LC (HPLC/MS). Table 18 summarizes representative papers using hyphenated techniques.

A newly developed scan function and methane gas control system has enabled classical chemical ionization (CI) spectra to be obtained in the IT, thus allowing direct comparison with reference spectra developed on magnetic and quadrupole instruments. Gas chromatography ion-trap mass spectrometry (GC/IT/MS) is used for the determination of diclofop-methyl and fenoxaprop-ethyl in fruit and vegetable matrices and of fluazifop-methyl in soil.

Mass selective detection (MSD), using either full-scan mode or SIM, can be employed to achieve selective detection of target pesticides in the presence of a complex matrix. MSD is a highly sensitive and specific technique suitable for environmental organic analysis. The most widely used technique for ArPP residue analyses is MSD with EI ionization. Quantification is usually achieved with the SIM technique. With this technique selectivity is also improved. Lee et al. have determined diclofop and haloxyfop in groundwater; after esterification with 2,2,2-trifluoromethanol, the esters are identified by GC with MSD in full-scan mode. In the method proposed by Butz and Stan, for the simultaneous determination of diclofop, fenoxaprop, fluazifop, haloxyfop, and quizalofop in tap water and groundwater, all MS measurements are performed with MSD combined with GC in full-scan mode. MSD in full-scan mode is also utilized for the determination of fluazifop and fluazifop-butyl in groundwater and of quizalofop-ethyl in fruit and vegetables.

Figure 9 shows a SIM chromatogram obtained in NI discharge on electrospray interface coupling HPLC to MS of a soil sample spiked with fluazifop, haloxyfop, and diclofop.

#### 5.3.4 Other Techniques

IAs are now being seen as useful supplements to classical chromatographic analytical systems. Schwalbe et al. describe the development of enzyme IA and fluoro-IA for the herbicide diclofop-methyl in soil, urine,
serum, wheat, soybeans, and sugar beet. To produce antibodies against the herbicide, rabbits were immunized with a conjugate of diclofop acid and bovine serum albumin, which was prepared by use of a water-soluble carbodiimide. The resulting antisera showed a high specificity towards the (dichlorophenoxy)phenoxy moiety of the herbicide, which was demonstrated by the determination of the cross-reactions of structurally related compounds.

6 DIPHENYL ETHER HERBICIDES

6.1 Chemical and Physical Properties

The p-nitro DPHE herbicides are commonly known as the DPhE herbicides. This class of herbicides is mainly composed of esters, but a few compounds are acids or have an acidic behavior, with pKₐ values between 2.7 and 3.8. They are yellow to brown crystals,
presenting in some cases a slightly aromatic odor. All compounds of this class are stable in slightly acid or slightly alkaline media (pH 5–9), but are hydrolyzed quite rapidly above pH 9. The exception is fomesafen which is stable even at pH 11. DPhE herbicides have been subjected to many studies in order to understand their mode of action. Initial studies into the mechanism of action of these compounds suggested they were interfering with some aspect of photosynthetic electron transport. Then Bugg et al. obtained evidence

</table>
which indicated the site of inhibition by the DPhE was in the plastoquinone-Cyt f region between PS-I and PS-II. However, there is evidence to indicate the inhibition of electron transport is a secondary effect.\(^\text{75–81}\) The most recent studies have determined that the site of action is protoporphyrinogen oxidase, and that the R group at the 3’ position of the DPhE molecule is an absolute requirement for the short term (8h) expression of herbicidal activity.\(^\text{82}\) However, the nature of the R group is also important.\(^\text{82}\)

Structure/activity studies have shown that the highest biological activity of DPhE is generated by the substituents 2-Cl, 4-CF\(_3\), 4-NO\(_2\) and various structures in the 3’ position (see Table 19). DPhE derivatives having oxime substituent groups at the 3’ position were found to exhibit high herbicidal activity and soybean selectivity.\(^\text{83}\)

DPhEs are systemic contact herbicides, absorbed more readily by the foliage, and especially by the shoots, then by the roots with very little translocation. In some cases herbicide activity is enhanced by sunlight. DPhE symptomatology is necrosis of shoot and root meristems with rapid desiccation of stems and leaves following PoE treatment of sensitive species.

This class of compounds is mainly used for PrE or PoE control of a wide spectrum of annual broad-leaved weeds and grasses in soybeans, peanuts, rice, and cereals. Particular crops include also potatoes, carrots, peas, maize, peppermint, onions, and a variety of tropical and subtropical crops.

The WHO toxicity class is III for all compounds except lactofen, which is WHO IV. Tests conducted on rabbits have demonstrated that DPhEs can be slight to moderate eye irritant. From studies of oral application in rats,\(^\text{84}\) it appears that fast and almost complete absorption and excretion occurs. Multiple applications did not indicate a cumulative effect, which suggests these herbicides do not present a substantial hazard to aquatic or terrestrial wildlife.

The basic physical chemical and other properties of the DPhE herbicides are listed in Tables 20–22.

### 6.2 Analytical Method for Diphenyl Ether Analysis

#### 6.2.1 Extraction

The extractive methods for DPhEs from environmental and food samples are given in Table 23.

LLE is the method chosen by several authors\(^\text{37,84,85}\) for DPhE extraction from aqueous samples. In some work\(^\text{37,84}\) the sample is shaken with an immiscible organic solvent such as dichloromethane; Edgell et al.\(^\text{85}\) extracted acifluorfen at pH < 2 with ethyl ether.

Sorption on to a solid sorbent provides a useful method for the isolation of DPhEs from aqueous samples. The most common sorbent used in SPE is C\(_{18}\) bonded silica cartridges.\(^\text{39,41,43,45,86–88}\)

Junker-Buchheit and Witzenbacher\(^\text{89}\) have developed an alternative SPE sorbent material to extract bifenox from tap water. This adsorbent is based on a highly cross-linked, porous ethylvinylenzene–DVB copolymer and exhibits a unique adsorption efficiency due to its high specific surface area. The ability of this adsorbent (LiChrolut EN) is comparable to a conventional RP-18 solid phase. Increased attention has been devoted to carbon sorbents,\(^\text{87,90}\) in addition to those with an SiO\(_2\) matrix. GCB is a nonspecific sorbent and is generally hydrophobic. Contrary to the sorbents based on SiO\(_2\), this may be used without taking into account the pH of the treated solutions.

Comparisons of different sorbents for SPE are proposed. SPE materials and techniques (C\(_{18}\) Empore disks, polystyrenedivinylbenzene, C\(_{18}\) Bond Elut cartridges, and ENVI-Carb cartridges) have been compared for the extraction of bifenox from water.\(^\text{87}\) Hodgeson et al.\(^\text{91}\) evaluated C\(_{18}\) and polystyrene DVB resin disks for the extraction of DPhEs in aqueous samples. Fibers coated with PDMS or liquid crystals of PAC have been developed for the extraction of oxyfluorfen from water samples\(^\text{92}\) by SPME. SPME is an alternative technique that involves direct extraction of the analyte with the use of a small diameter optical fiber that has been coated with a polymeric stationary phase and housed in a syringe assembly for protection. SPME eliminates the separate concentration step from the SPE and LLE methods because the analytes diffuse directly into the coating of the SPME device and are concentrated there. XAD-2 has been utilized for the extraction of bifenox from river water.\(^\text{81}\)

DPhE residues in soil and food samples are traditionally extracted from the solvent with some physical assistance (sonication, shaking, homogenizing). The solvents used include acetone,\(^\text{51,53,94,95}\) acetonitrile,\(^\text{67,96}\) mixed methanol–water (3 : 1, v/v),\(^\text{62}\) dichloromethane–ethanol–acetonitrile (6 : 2 : 1, v/v),\(^\text{97}\) and methanol–0.1 mol L\(^{-1}\) NaOH (80 : 20, v/v).\(^\text{98}\)

Homogeneous sample pulp containing oxyfluorfen, prepared from fruit and vegetables of different water content with or without additional water, is adsorbed on the surface of activated Florisil to obtain a free-falling powder, which is extracted in a glass column with ethyl acetate or dichloromethane–aceton (9 : 1, v/v).\(^\text{59}\)

#### 6.2.2 Cleanup

The choice of cleanup technique closely depends on how the extraction was done; in other words, whatever else enters the extract determines the purification procedure.

PAC, polyacrylate; PDMS, polydimethylsiloxane; XAD-2, styrene–divinylbenzene copolymer.

LLP followed by column chromatography or SPE has been the most common cleanup procedure in DPhE analysis. Dichloromethane, hexane, and petroleum ether and dichloromethane are used in LLP. Hsu et al. have investigated the potential of a SPE cartridge, Florisil, and SPE-C18, to replace Attagel in the bifenox cleanup procedure for raw agricultural crops. SPE with a silica cartridge was used by Gennari et al. for the cleanup of the organic extracts of soil and water in acifluorfen determination. An alternative mode of SPE is the use of the “SPE disks”. Bao et al. reported the use of C18 Empore extraction disks for isolation and cleanup of oxyfluorfen in soil.

The most universally applicable cleanup of organic extracts of DPhE from soil, vegetables, and agricultural products is GPC. Separation is generally performed by using DVB-linked polystyrene gels, mostly Bio Beads SX-3. For the elution of DPhE herbicides, the mixtures cyclohexane–EtOAc (50:50, v/v) and cyclohexane–acetone (50:50, v/v) are used.

### 6.3 Determination

Once the sample has been extracted from its matrix, usually into a suitable solvent, it is then ready to be analyzed by the appropriate technique. Chromatographic methods, and in particular GC and HPLC, are the methods of choice. GC is often the first choice in the analysis of DPhEs because of their good response with ECD; however, DPhEs are also well analyzed by HPLC, and this...
is often used in conjunction with UV detection. GC or HPLC, coupled with MS, provides the analyst with a powerful tool for both determination and confirmatory analysis. Because of the good voltammetric behavior of fluoroglycofen, the mercury-drop electrode is also applied.

6.3.1 Gas Chromatography

Fused capillary columns with phases of different polarity have been used: (nonpolar examples are SBP-5,\(^{90}\) 5% phenylmethylsilicone,\(^{86}\) DB-5,\(^{59,84,91}\) 5% phenyl–95% methylpolysiloxane;\(^{85}\) low-polar examples are 65% dimethyl–35% diphenylpolysiloxane,\(^{37}\) SBP-608,\(^{41}\) 50% phenyl–50% methylsilicone,\(^{96}\) OV-17,\(^{93}\)); typical dimensions are IDs of 0.22–0.53 mm, film thicknesses of 0.25–1 \(\mu\)m, and lengths of 12.5–60 m.

Some derivatization methods have been developed to improve the sensitivity and the peak-tailing situation in the case of acifluorfen and fluoroglycofen. The most used derivatization procedures are with diazomethane\(^{85,90,91}\) 2,2,2-TFE,\(^{37}\) pentafluorobenzyl bromide,\(^{59,43}\) and methyl, ethyl, and butyl chloroformate.\(^{41}\) As all DPhEs bear a chlorine heteroatom, the most used detection system is ECD.\(^{37,41,59,85,86,90,91,93,96}\)

Oxyfluorfen in water\(^{86}\) is determined by GC with ECD and flame photometric detection (FPD). A GC/AED system\(^{84}\) is used to analyze nitrogen-containing oxyfluorfen herbicides. The use of GC linked to AED offers an alternative to GC/MS for unambiguous determination of unknowns. The coupling technique was shown to be a very selective tool with element-characteristic chromatograms acquired using different element emission lines, thereby enhancing the selectivity of the method for environmental monitoring.

Figure 10 illustrates chromatograms by HPLC/UV and GC/ECD of a water sample spiked with acifluorfen.

Table 24 summarizes the column, mobile phase, detector, and DLs currently employed in routine DPhE residue analysis.

6.3.2 High-performance Liquid Chromatography

The usual way to obtain a good separation of acidic DPhE in GC is by chemical derivatization. HPLC is the method of choice for ionic compounds, acifluorfen, fluoroglycofen, fomesafen, and bifenox acid, which are not amenable to GC.

An RP/HPLC column containing \(C_{18}\) bonded silica sorbent\(^{45,85,89,90,97–99}\) is used for analytical separation. Narrow-bore (3 mm ID) columns and 3 \(\mu\)m particles\(^{87,99}\) have been applied in recent studies. For the elution, a mixture of acetonitrile and aqueous solution is used in isocratic mode.\(^{45,97–99}\) Gradient elution with acetonitrile and water modified with TFA\(^{90}\) or ammonium acetate\(^{87,89}\) have also been utilized. Buffer solutions with the pH-adjusted to below the \(pK_a\) values of the acidic DPhE are prepared from TFA,\(^ {90}\) \(\text{H}_3\text{PO}_4\),\(^ {97,98}\) and \(\text{CH}_3\text{COOH}\).\(^ {45}\)

UV detection, in the range 206–296 nm, is the most popular detection method in the analysis of DPhE residues.\(^ {45,85,90,97–99}\) In the determination of bifenox from tap water\(^{89}\) an increase of confirmation ability has been achieved with DAD technology. Zhou and Miles\(^{99}\) have demonstrated that oxyfluorfen can be determined selectively in crops by PCD. PCD and UV liquid chromatographic detectors also are evaluated.

The analytical conditions for HPLC analysis are presented in Table 25. Figure 11 shows a chromatogram of a soil extract of bifenox and its main metabolite, bifenox acid, using an UV detector.

### 6.3.3 Hyphenated Techniques

Although GC and HPLC are widely accepted for the residual analysis of DPhE, the need for compound identification cannot be overemphasized. This is particularly necessary for soil and agricultural products in which peak overlapping or unresolved peaks originating from matrix interference exist.

Table 26 summarizes the characteristics and the DLs of hyphenated techniques used for DPhE herbicide determination and confirmation in environmental and food samples.

GC/MS has become the preferred analytical technique. DPhE herbicides have been determined by GC/MS directly or after the preparation of derivatives.
GC/MS in EI mode in TIC was used for monitoring oxyfluorfen,\(^{92}\) and acifluorfen\(^{41}\) in water samples, bifenox and oxyfluorfen\(^{67}\) and bifenox\(^{53}\) in agricultural products. Capillary GC with MSD employing SIM with time window programming were developed for acifluorfen,\(^{39,43}\) and chlornitrofen\(^{88}\) in drinking water and surface water.

GC/MS of DPhE residue analysis has been largely restricted to quadrupole instruments. Another technique that has been used for DPhE quantitation is that of GC/IT/MS. The components of an IT system are much less complicated than the instrumentation previously mentioned and rely on electronic control to obtain mass spectra. Bao et al.\(^{62}\) utilized IT/MS for testing oxyfluorfen in soil. The same technique was used by Cairns et al.\(^{51}\) and Tuinstra et al.\(^{94,95}\) for bifenox and fluoroglycofen determination in agricultural products.

One potential approach to the determination of acifluorfen in water\(^{90}\) is the use of HPLC/MS in conjunction with interface particle-beam. In this work, to improve the sensitivity, the PB target zone inside the ion source is coated with a Teflon layer. It is well known that when acidic pesticides enter the ion source, they undergo decomposition due to the high temperature of the ionization chamber (>200°C). This inconveniently causes a reduction in sensitivity and an unwanted memory effect. Coating the ion source reduces adsorption and decomposition, and enhances the gas-phase conversion of analytes.

### 6.3.4 Other Techniques

Classical DC polarography and fast-scan differential pulse voltammetry were applied to study the reduction mechanism of fluoroglycofen-ethyl at a dropping mercury electrode (DME) and at a static mercury-drop electrode

---

</table>
(SMDE) in a medium of 47–49% (v/v) or 10–20% (v/v) dimethylformamide. The nitro groups were reduced to hydroxylamine derivatives, or further to the corresponding amines, depending on the type of compound and the solution acidity. The determination of nitropesticide was performed using FSDVP and adsorptive stripping voltammetry (AdSV) in model samples. The DLs were found both experimentally and by calculation from regression analyses. According to the experimental condition their values were in the range 17–160 ng mL$^{-1}$ or 0.1–2.8 ng mL$^{-1}$ for FSDVP or AdSV, respectively. The nitropesticide in artificially contaminated soils was determined after two or three extractions with acetone.

Figure 12 shows a reconstructed ion chromatogram of an extract of crops spiked with bifenox. Selected-ion chromatograms of standards, blind, and recovery river water samples showing the ion trace for each selected masses are presented in Figure 13.

The important role of high-performance liquid chromatography (HPLC) in pesticide residue analysis (PRA) is presented. Based on the experience and view of the author, a number of reliable and robust liquid chromatography (LC) approaches and methods have been selected to highlight the favorable features of this technique in this field of analysis.

Reversed-phase liquid chromatography (RPLC) with ultraviolet (UV) detection mode is most widely adopted, owing to its ability to perform efficient separation of very polar to apolar pesticides and the universal character of the detection mode. Therefore, a large part will deal with reversed-phase liquid chromatography/ultraviolet (RPLC/UV) applications showing its excellent separation performance and detectability of compounds not directly amenable to gas chromatography (GC).

Another important feature of RPLC is the possibility of including sample pretreatment steps such as sample concentration and/or cleanup in the analytical procedure. The very good compatibility with aqueous samples or extracts easily permits RPLC on-line sample loading (trace enrichment) by means of column switching, allowing fully automated procedures. It will be shown that, depending on whether the first column is a low- or a high-resolution column, two different modes of column switching, solid-phase extraction (SPE) to LC and LC to LC, are adopted in the determination of pesticides. The type of columns and materials, the advantages and the application range of both column-switching modes is discussed in detail. Attention will be paid to method development including both the straightforward trial-and-error approach and more systematic method development procedures.

The more selective/sensitive detection modes, fluorescence detection (FD) and mass spectrometry (MS) as applied in pesticides residue analysis will be discussed with emphasis on the increasing importance of MS for identification and quantification of polar pesticides in various types of samples.

Finally, the use of LC methods involving normal-phase liquid chromatography (NPLC), low-resolution RPLC and gel permeation chromatography (GPC), will demonstrate the powerful sample pretreatment feature of LC prior to gas chromatographic analysis.
1 INTRODUCTION

The major task of the analytical discipline PRA is to provide reliable and, moreover, cost-effective methods for the identification and quantification of hundreds of pesticides with large differences in physicochemical properties in very different types of matrices. The introduction of high-resolution capillary GC employing fused silica columns in the early 1980s, combined with the commercial availability of several sensitive and, moreover, selective GC detectors, contributed greatly to the rapidly increasing popularity of GC-based procedures for PRA. These favorable aspects make capillary GC, today, the major analytical and productive technique for this type of analysis. For example, in the Netherlands a multiresidue method (MRM) based on GC with MS detection used for regulatory purposes\(^1\) covers the determination of 270 pesticides in foodstuffs from a total of 465 mentioned in the Dutch Regulation on Pesticides in Foodstuffs.\(^2\)

An overview of most pesticides which are not covered by the gas chromatography/mass spectrometry (GC/MS) method is given in Table 1. These pesticides and their corresponding chemical families are characterized by low volatility, high polarity and/or thermal instability making them not directly amenable for GC. For this type of analyte LC can be a good alternative. Most of these analytes can be nicely separated and efficiently detected by means of RPLC with UV detection, while GC analysis requires an often complicated derivatization procedure prior to separation. The availability of robust and more selective fluorescence and mass spectrometric detectors for LC further enhances the practical value of this separation technique.

It must be stressed that, because it is possible to combine high sensitivity and selectivity (confirmation), GC/MS procedures involving a derivatization step are still attractive and frequently applied for the thermostable compounds such as phenoxy acids. In fact, one must emphasize the complementary aspect of LC to GC. For example, LC can be a more viable way for the determination of thermolabile compounds such as carbamates or analytes difficult to derivatize, such as quaternary ammonium compounds.

Beside the advantageous use of HPLC for (very) polar pesticides, there are, as displayed in Figure 1, other important considerations for selecting HPLC in PRA. For example, in monitoring and/or indicative studies rendering a relatively low number of positive samples, the availability of a screening method(s), e.g. RPLC/UV for the determination of polar pesticides, can be cost-effective. The ability of RPLC to separate apolar and very polar analytes in one run makes it possible to determine pesticides simultaneously with their usually distinctly more polar metabolites.

RPLC is very compatible with aqueous samples, which enables sample pretreatment steps to be included by means of column switching in the analytical procedure, allowing fully automated (on-line) methods for the determination of pesticides in water samples. Furthermore, direct injection of a large volume of water makes RPLC attractive for other types of study, e.g. to study the formation of metabolites and transformation products (TPs) of pesticides at real-life trace levels (in-line analysis) or the at-site monitoring of pesticides in suspected water locations.

Other LC modes like GPC or NPLC have proven to be efficient for the cleanup of difficult matrices, e.g. fatty food products or soils. The high potential for automation provides semi and/or fully automated procedures effectively replacing the conventional laborious and less accurate open-column LC procedures.

Concerning methodology one can discriminate between single residue methods (SRMs) and MRMs. From an economical point of view, MRMs are highly desirable because the detection and quantitative determination of a series of pesticides in one run considerably reduces the cost of analysis.

However, multiresidue analysis of pesticides is faced with several problems. Firstly PRA has to cover the two disciplines including public health and environmental protection. Consequently, one has to deal with a large variety of sample types of widely diverging composition making it difficult to include the multimatrix aspect into an MRM. There is no guarantee that a method developed, for example, for the determination of chlorophenoxy acids in soils, will work for some foodstuffs, so different MRMs are required for the same group of pesticides.

Another difficulty is caused by regulations in relation to the different matrices. For example, maximum residue levels (MRLs) of pesticides in foodstuffs arranged by the Dutch legislation\(^2\) are in agreement with the directives of the European Community (EC) and comply with the recommendations of the Codex Committee on Pesticide Residues (CCPR). These levels are based on scientific evaluations estimating the acceptable daily intake and the expected residue level in food when a pesticide is used according to good agricultural practice. As a result, for a single pesticide MRL ranges can be encountered which comprise several orders of magnitude posing a severe problem in multiresidue analysis. For most environmental samples and drinking water, the MRLs are generally much lower than for food samples. The EC directive for drinking water\(^3\) states that the concentration of pesticides and related products should not exceed the level of 0.1 µg L\(^{-1}\) (ppb) for individual compounds and 0.5 µg L\(^{-1}\) for total pesticides. This essentially means that methods of analysis are required which are about 1000 times more sensitive than those for foodstuffs.

\textsuperscript{a} Data from van Zoonen.\textsuperscript{11}
Thus for the same group of compounds, different MRMs for different matrices and corresponding MRLs are sometimes encountered in literature.

The large variety of physico-chemical properties such as polarity, volatility, thermostability and, occasionally, molecular weight of the pesticides makes the simultaneous chromatographic separation and detection more difficult and counteracts the availability of MRMs.

Because of productivity most attention will be given to MRMs. However, the availability of fast SRMs can be attractive in this field of analysis. Especially, in survey programs based on use patterns and ad hoc requests for a certain pesticide/matrix combination, screening methods are efficient. For this type of analysis it is even better to have efficient method development strategies available.

Not all methods that have been published can be included and, hence, a comprehensive overview is not given. For such information, excellent textbooks reviewing the LC analysis of pesticides residues in foodstuffs and environmental samples are available.

Here, the versatility and feasibility of LC in PRA is demonstrated by making a careful selection of various types of current state methodologies encountered in PRA. After a general section on the LC analysis of pesticides, the further content is based on different LC modes. Within these modes further discrimination will be made as regards analytes and matrices.

2 REVERSED-PHASE LIQUID CHROMATOGRAPHY WITH ULTRAVIOLET DETECTION

2.1 General Aspects

RPLC is a suitable technique for the determination of polar analytes in water, since derivatization is usually superfluous and in the analysis of aqueous samples the mobile-phase system is fully compatible permitting automation of the analytical procedure. The wide application range, long-term stability, ease of use, low cost and improved selectivity (diode array) means that the combination of UV detection and RPLC is still widely used in residue analysis.

The chromatogram displayed in Figure 2 nicely illustrates RPLC performance. Employing an injection volume of 200 µL, an efficient elution and separation of eight carbamate pesticides is obtained in less than 10 min employing a 100 x 4.6 mm column packed with 3 µm Microspher C_{18}, and an isocratic elution. The chromatogram of Figure 2 also shows limitations. Under these conditions the number of peaks that can be separated in one run is limited, increase of separation power by extending the length of the column will be restricted by column pressure, and the longer retention time inversely affects sensitivity, as shown in the chromatogram of Figure 2. Gradient elution enhances the total number of peaks that can be separated in one run and effectively controls band broadening of analytes. However, a severe baseline drifting usually occurs in the trace analysis employing nonselective UV detection at low wavelengths.

The problems usually encountered in RPLC/UV analyses of residues of pesticides in samples and extracts is shown by the simulated chromatogram in Figure 3. The most common problem is caused by abundantly present early eluting sample constituents indicated as S1. In many cases S1 can be largely removed via low-resolution cleanup such as off-line SPE or on-line with solid-phase
HPLC METHODS IN PESTICIDE RESIDUE ANALYSIS

Figure 3 Simulated chromatogram of sample interferences occurring in the RPLC/UV trace analyses of pesticides. S1, S2 and S3, sample interferences; A1, A2 and A3, analytes.

HV, high pressure valve; S, solvent selection valve; PC, trace enrichment (exchangeable) column; P, isocratic LC pump; GP, gradient LC pump; AC, analytical column; DAD, diode array detection, UV-diode array detector; WS, workstation; SDU, solvent delivery unit; PROSPEKT, valve and cartridge switching system.

extraction/liquid chromatography (SPE/LC). However, in the case of analytes with a polarity close to the range of the large excess of interfering constituents such a cleanup will not be sufficient.

Compounds with longer retention times than the analytes, S3, do not really interfere, but cause an unfavorable increase of the time of analysis. Tuning the selectivity by small changes in mobile-phase compositions, e.g. eluotropic strength or type of modifier, is usually applied to improve the separation caused by interferences of type S2.

The high compatibility between mobile phases and aqueous samples and extracts, and convenient instrumental operation provide an important feature of RPLC, that is, column switching. The use of more than one column offers the possibility to perform on-line sampling and/or cleanup which enhance sample throughput, sensitivity and/or selectivity in a cost-effective way.

In most cases, the sample preparation step is performed on a small precolumn (PC) installed in a column-switching system which permits the analytes to be desorbed automatically, after sample loading and a washing step, to the analytical LC column for separation and detection. Until the early 1990s this technique was usually named precolumn/liquid chromatography (PC/LC). Nowadays (and also here) the term SPE/LC is used for the various types of system using PCs, disposable cartridges and/or solid-phase extraction disks (SPEDs) coupled on-line to the analytical column.

In SPE/LC, PCs with dimensions of, typically, 5–10 mm (L) x 2–4.6 mm ID are usually employed. In order to enable fast sampling, PCs are packed in most instances with 10–40 µm material. The small size reduces cost, and favors a fast desorption to the analytical column. A typical setup of a fully automated solid-phase extraction/liquid chromatography/diode array detection (SPE/LC/DAD) system is shown in Figure 4. This SPE/LC set-up is called SAMOS (System for Automated Monitoring of Organic Compounds in Surface Water) and was specially developed as an early warning system for the pollution control of surface waters. (6,7)

It will be obvious that hydrophobic type SPE/LC is a highly efficient trace-enrichment procedure, but does not contribute much to increase selectivity. For the determination of some specific groups of pesticides, sorbents with a different retention mechanism such as ion exchange have been successfully applied to improve selectivity in SPE/LC. (8)

Coupled column reversed-phase liquid chromatography (LC/LC) employing a full size separation C18 column as the first column (C-1) is a good alternative to improve selectivity in hydrophobic column switching. (9–11)
is illustrated in Figure 5 which schematically shows the important steps involved in the heart-cutting technique. As well as using the separation power of the first column (C-1) to remove effectively interferences of types S₁ and S₃, this approach acts as an analyzer. The high sample throughput of LC/LC originates from the fact that sample injection is performed in the high-pressure mode by an autosampler equipped with a large volume loop and a syringe pump. The insertion by the injector of an air gap in front of and after the sample provides fast and accurate LVI with a minimal consumption of sample. This feature allows the use of rather small autosampler vials and facilitates the processing of large series of samples.

The major advantage of LC/LC is the high resolution of C-1, which contributes to the enhancement of the selectivity by removing a large part of the early eluting interferences, S₁. Another crucial feature of LC/LC is the transfer volume, or the time that C-1 is coupled on-line to C-2. Obviously, the size of the transfer volume (A) will be inversely proportional to selectivity, making LC/LC most powerful in single-residue analysis. However, the key to success in the enhancement of the selectivity in the analysis of polar analytes, especially in environmental samples, is the effective removal of early eluting interferences. Therefore, the development of MRMs involving larger transfer volumes, which would lead to less selectivity, can still be quite attractive.

Starting with RPLC/UV method development for successful applications in trace analysis of pesticides, methods will be discussed highlighting the possibilities, features and limitations of RPLC, SPE/LC and LC/LC with or without off-line sample pretreatment procedures.

Next, LC methods in combination with more selective detection, FD and MS detection, will be discussed. Finally, with emphasis on cleanup, other types of LC applications will be presented.

2.2 Practical Method Development

The discussion of the important RPLC/UV parameters will be done by following the scheme of Figure 6 which is based on the author’s experience, and used in LC and LC/LC methods developed for the determination of polar pesticides in environmental samples.\(^{9-11}\)

The possibility of an RPLC/UV method is determined by the applicable UV absorption (wavelength, \(\lambda\) (nm) and molar extinction coefficient, \(\varepsilon\) (L mol\(^{-1}\) cm\(^{-1}\))) and the retention (capacity factor, \(k\)) of the analyte(s) from pure water onto the C\(_{18}\)-type stationary phase. With insufficient
ultraviolet/visible (UV/VIS) absorption/selectivity ($\varepsilon$ values of less than ca. 1000 $\text{L mol}^{-1}\text{cm}^{-1}$ and $\lambda < 200\text{nm}$) and/or an essential absence of retention on a C18-bonded phase ($k$ values of less than ca. 1), the successful development of an RPLC/UV procedure for trace level analysis becomes highly unlikely.

RPLC/UV information on pesticides acquired at our laboratory is given in Table 2. In this Table the UV absorption maximum was selected as a good compromise between selectivity and sensitivity as encountered in this field of analysis. Beside UV sensitivity ($\varepsilon$), the peak elution volume of the analyte inversely contributes to the degree of analyte detectability. Therefore, information on the elution of the analyte, expressed as the column efficiency ($N$), is included in Table 2. The large difference in efficiency ranging from 280 (cypermethrin) to 5100 (chlorbufan) clearly emphasizes the importance of this parameter to sensitivity.

Figure 6 Scheme of straightforward LC- and LC/LC/UV method development in PRA.

$^a$ Determined on a 50 × 4.6 mm ID packed with 3μm C$_{18}$ and mobile phase of acetonitrile (ACN) (modifier) –0.03 M phosphate buffer, pH 3, at a flow of 1 mL min$^{-1}$.
$^b$ Number of plates on the column measured as $(l_n/a)^2$.
$^c$ Methanol in water.
$^d$ ACN in 0.2% ammonia water.
CAAL, chloroallylalcohol; ETU, ethylenethiourea; PCP, pentachlorophenol.

As indicated in Figure 6 the next step is to select adequate RPLC parameters concerning separation power and elution conditions. These parameters are determined by the dimension of the column (LC) or columns (LC/LC) and the mobile phases ($M_i$). It must be stressed that, from an efficiency point of view, one should not optimize the method beyond a certain degree: the LC system must be kept as simple as possible. For example, if sample extracts are clean enough, column-switching can be omitted. However, trace analysis requires in most cases an efficient cleanup of sample or extract.

For the on-line cleanup, C-1 must provide sufficient separation to remove a major part of the abundantly available early eluting matrix constituents, S1, prior to elution of the analyte. Therefore a column with high separation power is attractive. However, an unnecessary increase of separation power and dimension of the column must be avoided; the peak elution volume, which is inversely proportional to the sensitivity in detection of the analyte, should be kept as low as possible. An increase of the column dimension will also increase the reconditioning time (if necessary) of C-1 between analyses. In general, an eluotropic strength of M-1 should be selected such that the capacity factor of the analyte is in the range of 1 < $k'$ < 5, yielding a cleanup volume of at least two times the dead volume of the column ($V_0$) to remove a large part of the excess of early eluting interferences.

Especially in the analysis of compounds with little C$_{18}$ retention, it is favorable to select a second column (C-2) with a higher separation power than C-1. This will provide some flexibility when optimizing the eluotropic strength of M-2 in order to reach a proper compromise between the required separation efficiency on the second column, and the desired peak compression (sensitivity of detection). It must be emphasized here, that the eluotropic strength, $\varphi$ (fraction of organic of modifier), of M-1 must never exceed that of M-2 ($\varphi_{M1} \leq \varphi_{M2}$). During this part of the optimization one can, if required, tune selectivity by taking another type of hydrophobic column packing material or one from a different manufacturer or, in most cases firstly, by changing the mobile-phase constituents such as type of modifier, buffer and pH. The latter parameter can play a crucial role for the determination of acidic compounds in environmental water and soil samples.

In case of the on-line analysis of aqueous samples the attainable sensitivity is determined by LVI of standard solutions in HPLC-grade water. This is usually done by connecting C-1 to the UV detector which also provides the establishment of cleanup and transfer volumes. The maximum allowable sample injection volume, that is the volume that can be injected without excessive band
broadening of the analyte, largely depends on the C$_{18}$ retention of analyte. For example, the small C$_{18}$ retention of polar compounds such as CAAL and ETU (see Table 2) makes focusing of the analyte on the top of the column impossible, and because of migration of analyte during injection, band broadening rapidly starts to increase with increasing injection volume. In general, the start of peak deformation of the analyte upon injection on C-1 is selected as a criterion for the maximum allowable injection volume.

As demonstrated for bentazone in Figure 7, for analytes with sufficient retention (k > 100 in pure water as the mobile phase), RPLC allows LVI without additional band broadening. If sufficient sensitivity cannot be obtained with a large volume loop injection below 8 mL, then an off-line concentration step such as SPE or liquid extraction will be necessary.

Finally, the total procedure is used to analyze real-life water samples and/or extracts. Insufficient selectivity can be improved by either re-adjustment of LC conditions or by changing the selectivity of the stationary and/or the mobile phase.

2.3 Systematic Method Development in Coupled Column Liquid Chromatography

The method development procedure discussed above is carried out in a rather straightforward way on the basis of trial-and-error experiments. The task of finding the adequate LC/LC conditions for separation between analytes and/or interference can be very difficult for the case of multiresidue analysis including compounds with a large and/or small difference in retention. For such cases, sophisticated method development procedures based on simulation and/or calculation were developed in order to avoid excessive experimental work.\textsuperscript{13–15}

As a first step towards the development of dynamic MRMs for pesticides with LC/LC a simulation programme was developed.\textsuperscript{13} It was based on a diffusion model; the main objective was an accurate prediction of retention times and peak volumes in order to formulate in a more effective way boundary conditions for development of MRMs using LC/LC.

Another step forward was to include the essential criteria involved in the optimization of step gradient elution in MRMs,\textsuperscript{14} namely:

1. The first-eluting analyte must have a retention which is at least twice as large as that of the unretained compound (similar to SRM approach).
2. The total time of the chromatographic run should be kept relatively short (for sensitivity and sample throughput).
3. The resolution (Rs) between two adjacent peaks must be at least 1.2 to prevent problems due to UV wavelength switches and/or changes in the mobile-phase compositions.
4. The number of steps during gradient elution should be minimized to reduce baseline distortions and the complexity of the LC system.

Finally, a convenient and automated optimization procedure OPTIME Version 3.1 has been developed.\textsuperscript{15} OPTIME Version 3.1 is based on the use of analytical equations for the prediction of chromatographic data (retention and peak volume) of analytes eluting under one- or two-step-gradient LC/LC conditions. The procedure is a constructed worksheet (Microsoft\textsuperscript{®} Excel) and can be applied as a calculation and/or an optimization procedure.

In comparison to simulation, the developed calculation procedure enables a more rapid search for suitable
conditions for on-line cleanup and separation of analytes using coupled-column RPLC and is therefore highly productive and flexible.\textsuperscript{15}

### 2.4 Liquid Chromatography/Ultraviolet Methods

The wide scope of both retention and detection of RPLC/UV enables fast separation and determination of many and various types of pesticides. Because of this favorable feature, RPLC/UV is frequently used in providing rather easy SRMs for the screening/monitoring of a limited number of target pesticides. In this context, RPLC/UV is attractive for use in the set-up of a screening method for recently developed polar pesticides.\textsuperscript{16–20} The assay of the thermolabile, polar and relatively new insecticide imidacloprid in water and soil was rapidly performed with an RPLC/UV (270 nm) method using a 250 \( \times \) 4.6 mm ID C\textsubscript{18} column with a mobile phase of methanol–water (20:80, v/v) at a flow rate of 1.5 mL min\(^{-1}\). Extraction was performed with either SPE on 500 mg C\textsubscript{18} columns (water) or with ACN (soil) and the analyte was determined in the uncleaned extracts to a level of 0.5 \( \mu g \) L\(^{-1}\) and 5 \( \mu g \) kg\(^{-1}\) in water and soil, respectively.\textsuperscript{16} The simultaneous determination of six imidazolinone herbicides in natural waters was successfully carried out with off-line SPE (0.5 to 1 L of sample on 500 mg Carbograph-1) followed by RPLC/UV (240 nm); the analytes were separated on a 5 \( \mu m \) C\textsubscript{18} column (250 \( \times \) 4.6 mm) and a gradient elution with ACN, water and formic acid in water as mobile-phase constituents; the method includes the analysis of soils and confirmation of analytes with liquid chromatography/electrospray mass spectrometry (LC/ESMS).\textsuperscript{17} A relatively new herbicide, thioazopyr and its mono-acid metabolite were assayed in groundwater with a simple method using SPE on graphitized carbon black (GCB) cartridges for sample treatment and RPLC/UV (220 nm) for instrumental analysis of the extracts obtained.\textsuperscript{18}

Another relatively new class of herbicides are sulfonylurea herbicides characterized by low application rates and low toxicity to mammals. A number of RPLC/UV-based methods have been reported on the efficient determination of these herbicides in water and/or soil.\textsuperscript{19,20} The combination of microwave-assisted solvent extraction (MASE) and RPLC/UV (226 nm) proved to be a convenient technique for the multiresidue analysis of sulfonylureas (5 tested) in soils down a level of at least 5 \( \mu g \) kg\(^{-1}\).\textsuperscript{19} After MASE (10 min), part (10 mL) of the organic solvent (dichloromethane–methanol, 90:10) was evaporated and the redissolved residues were analyzed with RPLC/UV in less than 15 min without additional cleanup. An important aspect was that samples with aged residues (60 days at 4 \( ^\circ \)C) were included in the method validation.\textsuperscript{19}

A highly sensitive and rather selective high-performance liquid chromatography/ultraviolet (HPLC/UV) (230 nm) method for the determination of seven sulfonylureas in water was developed by Di Corcia et al.\textsuperscript{20} Both selectivity and sensitivity were obtained by employing off-line SPE on 500 mg Carbotrap 4 cartridges. This type of cartridge allows very large volume sampling (up to 4 L tested) without breakthrough of the sulfonylureas and stepwise elution of acid compounds. The latter feature avoids co-elution of humic acid interferences when using dichloromethane–methanol (80:20, v/v) acidified with acetic acid (10 mmol L\(^{-1}\)) as the solvent for desorption; confirmation of compounds was performed with electrospray mass spectrometry (ESMS) detection.\textsuperscript{20}

In the case of relatively large molecules, e.g. antibiotics, and/or very polar or ionic pesticides such as bipyrinediyimine herbicides, RPLC provides an efficient separation. For example, efficient RPLC/UV methods have been developed for the residue analysis of warfarin in eggs\textsuperscript{21} and spinosad and its metabolites in vegetables and fruits.\textsuperscript{22}

Ion-pair/reversed-phase liquid chromatography (IP/RPLC) provides an efficient separation of ionic organic compounds. Despite the inherent LC pump wear of pistons and seals, IP/RPLC with UV detection is still the chosen technique for the determination of bipyrinediyimine-type herbicides. Dedicated methods are available for the determination of diquat and/or paraquat in various type of matrices including mammal tissues\textsuperscript{23} and biological fluids\textsuperscript{24,25} and mammal tissue.\textsuperscript{26} Because of their different UV spectra, detection is carried out at 257 and 308 nm for paraquat and diquat, respectively. IP/RPLC with UV detection at 292 nm has been successfully applied for the simple, rapid and sensitive assay of 10 benzimidazole residues in milk.\textsuperscript{26} The method based on a pH-based liquid–liquid extraction (LL/E) with ethyl acetate/buffer and the LC/UV analysis of uncleaned extracts enables determination of all compounds to a level of 5 \( \mu g \) L\(^{-1}\) with overall recoveries ranging between 70 and 100%.

Di Corcia et al.\textsuperscript{27,28} developed a MRM for the monitoring of 89 pesticides in environmental waters. The group comprises base-neutral and acidic pesticides from various classes, e.g. carbamates, triazines, phenylureas, phenoxy acids and phenols. The method is based on the use of off-line SPE and HPLC/UV. In this method the role of the SPE on 300 mg Carbotrap B cartridges is important. This GCB material allows sampling of water at a high-speed (120–130 mL min\(^{-1}\)) and provides selectivity by separating base-neutral from acidic analytes by means of a step-wise elution. Chromatographic analysis was performed on 250 \( \times \) 4.5 mm ID columns packed with different 5 \( \mu m \) silica-bonded materials. For the base-neutral fraction (71 pesticides), the primary column contained a LC-C\textsubscript{18}-DB (de-based) packing and the confirmation column contained a LC CN (cyano) packing. The acidic fraction (18 compounds) was separated on LC-C\textsubscript{18}. The
Separation of analytes was performed by optimized gradient elutions using ACN and buffered water as mobile constituents. UV detection was carried out at 220 nm and 230 nm for the determination of base/neutral and acidic pesticides, respectively. The limits of quantification (5 times the limit of detection LOD) were lower than 0.1 µg L⁻¹ for 84 pesticides and recoveries ranged between 80 and 105% with relative standard deviations (RSDs) below 10% for recoveries at low levels. The procedure was further modified by extending the analysis to very polar pesticides and metabolites by using 1 g GCB cartridges designed to perform re-extraction of the analytes in the back-flush mode.²⁹

A general problem encountered in the RPLC/UV analysis of acidic pesticides in environmental samples is the presence of a broad hump in the chromatogram caused by the presence of co-extracted humic and fulvic acids. As will be discussed below, column-switching procedures employing sorbents with a different selectivity are available to improve significantly the chromatographic analysis. An effective off-line SPE procedure has been presented³⁰ employing cartridges packed with 200 mg of SDB-1 sorbent (styrene–diphenylbenzene). Beside the sufficient retention capacity of polar pesticides such as oxamyl and triazine metabolites deisopropylatrazine (DIA) and deethylatrazine (DEA) this material also retained the tested acidic pesticides (7 compounds) in their ionic form. This feature allowed sampling (500 mL) of water at pH 7 and eliminated largely the humic interferences making it possible to determine with RPLC/UV (220 nm) a group of 17 various pesticides in river water to a level of 0.1 µg L⁻¹.

Immuno-affinity-based extraction procedures offer high selectivity. This is clearly demonstrated by Pichon et al.⁵¹,³² who developed immunosorbents for the selective SPE of phenylurea and triazine herbicides from environmental waters. The important advantage of the off-line immunosorbent is that it performs trapping of the majority of analytes of a chemical class (phenylurea, 9 out of 13; triazines, 6 out of 9), extending the scope of immunomethodology towards multiresidue analysis. The high selectivity is illustrated in Figure 8 showing the RPLC/UV (244 nm) analysis of phenylurea herbicides in extracts of surface water obtained after 200 mL of preconcentration on the immunosorbent cartridge.³¹

2.5 Solid-phase Extraction/Liquid Chromatography/Ultraviolet Methods

Fully automated SPE/LC methods using on-line trace enrichment, gradient elution and UV DAD were firstly directed to the multiresidue analyses of polar pesticides in various types of water.⁶,³³,³⁴ Trace enrichment (100–150 mL of sample) was usually carried out with

---

Figure 8 Off-line immuno-assay and RPLC/UV (244 nm) for the preconcentration of 200 mL of Seine River water (a) nonspiked and (b) spiked with 0.5 µg L⁻¹ of each of phenylurea herbicide on a cartridge containing silica bonded with anti-isoproturon antibodies. LC conditions: 250 × 4.6 mm ID 5 µm Supelcosil LC-18-DB column; ACN–water gradient elution consisting of 20 to 35% modifier from 0 to 52 min, 35 to 70% from 52 to 80 min, and 70 to 100% from 80 to 85 min. Peak assignment: (3) monuron, (5) chlortoluron, (7) isoproturon, (8) difenoxyuron (9) buturon, (10) linuron, (11) chlorbromuron, (13) neburon. (Reprinted with permission from Pichon et al., Anal. Chem., 67, 2541–2460. Copyright © 1995, American Chemical Society.)
an automated PC exchange system (Prospekt) using 10 × 2.0 mm ID disposable cartridges packed with 20 µm polymeric reversed-phase spherical packing (PLRP-S). Separation of analytes was accomplished on a 250 × 4.6 mm ID column packed with 5 µm C_{18} (DB) and gradient elution with ACN and 0.03 M phosphate buffer (pH 3) as mobile phase constituents. The effectiveness of DAD in providing very well matched UV spectra for confirmation of pesticides and or metabolites in European rivers, traced at levels between 0.05 and 1.4 µg L^{-1} has been clearly demonstrated. Direct automated evaluation of data integrated in the fully automated LC-system resulted in an early warning system called SAMOS which has been successful in the determination of 27 organic micropollutants at concentrations of 1 µg L^{-1} in surface waters. It is interesting to note here that for compounds amenable to GC the same automated sample pretreatment procedure was used, providing a solid-phase extraction/gas chromatography (SPE/GC) based SAMOS. The SPE/LC SAMOS approach was further optimized by a more efficient separation of analytes involving the use of a 150 × 4.6 mm ID column packed with 3.5 µm Zorbax SB-C_{18}, a column temperature at 43°C (buffering (pH of 7) of the mobile phase with ammonium acetate significantly improved the peak shape of some triazines. The improved conditions allowed the automated SPE/LC/DAD analysis of triazine and phenylurea herbicides in raw and drinking water with LODs ranging between 0.002 and 0.012 µg L^{-1}. Confirmation with UV DAD was accomplished, even at levels near to the LODs. Requiring an analytical run time of 65 min for adequate separation of analytes and the analyses of standards, the system is able to process about 10 samples per day.

Up to about 110 compounds representing many classes of polar compounds were determined on-line with SPE/LC/DAD. This study emphasized that beside important parameters such as sample pH, column temperature and elution conditions, the type of LC column was found to be the most important parameter. From the six columns tested the 150 × 4.6 mm ID column packed with 3.5 µm Zorbax SB-C_{18} provided the highest selectivity/sensitivity. The very good performance of DAD confirmation of phenolic compounds in case of baseline distortion caused by humic acid interferences is shown is Figure 9. Decrease of the base-line distortion in the first part of chromatogram was achieved by applying on-line dual PCs (both 10 × 2 mm ID, packed with 15–25 µm PLRP-S). With this approach, the highly polar compounds which showed breakthrough on the first PC were trapped on the second one while most of the humic substances are retained on the first one.

In comparison to PCs, hydrophobic membrane extraction disks (SPEDs) appeared to be a good alternative with respect to sorption, capacity, back-pressure and stability after repeated use. A simple leak-tight membrane disk holder offering flexibility in choosing type, size and number of disks was developed to perform on-line operation. Solid-phase extraction disk/liquid chromatography/ultraviolet/diode array detection (SPED/LC/UV/DAD) methods allowed the rapid trace level determination of three basic pesticides (carbendazim, chlorida- zon, simazine) and nine neutral pesticides (carbamates, phenylureas) in river and drinking water, respectively.

The simultaneous on-line determination of the diquat, paraquat and difenzoquat in water at levels of 0.1 µg L^{-1} was carried out with SPE/LC/UV. Sampling and separation of analytes was performed on Hypercarb-GCB or bare silica material employing sampling volumes of 50 (on GCB) or 200 mL (on silica), respectively.
A distinct advantage of on-line SPE systems is to improve selectivity by using SPE columns packed with an analyte(s) trapping sorbents of a different separation mechanism. One must take care that the desorption kinetics are fast enough to avoid a large loss of efficiency. For example, this drawback occurs in combining carbon materials, which have the best enrichment properties, with a C18 analytical column.\(^{(43)}\) Methods based on use of selective SPE sorbents have been developed for the fully automated analysis of chlorophenoxy acid herbicides in water by using either a PRP-1 and anion-exchange PC in series\(^{(8)}\) or a PC in combination with pH step-gradient from 2.8 (sampling) to 8.8 (desorption) followed by ion-pair LC separation at pH 8.8.\(^{(44)}\) Both methods allowed the determination of the acidic pesticides in tap water at levels between 15 and 30 µg L\(^{-1}\). For the on-line SPE/LC determination of a group of phenolic and neutral pesticides, interference of humic acid was significantly decreased by using a modified polymeric resin (o-carboxybenzoyl moiety) in combination with addition of sodium sulfite salt to the water sample.\(^{(45)}\)

A new development in improving selectivity of the on-line SPE/LC techniques is the use of pressure resistant immunosorbents for trace enrichment. Especially, the availability of material providing sufficient cross-reactivity to pesticides of a same chemical class makes this technique more attractive for use in multiresidue analysis. Based on this approach methods have been developed for the simultaneous on-line trace analysis of phenylurea herbicides in environmental water using a silica-based immuno\(^{(46)}\) or mixed-immuno silica-based sorbent.\(^{(47)}\)

Recently, Kok and Hiemstra\(^{(46)}\) presented an overview of their developed HPLC methods\(^{(1,48–51)}\) used in daily practice for the efficient screening of polar and/or thermolabile pesticides in fruits and vegetables. The five SPE/LC based methods are schematically presented in Figure 10 and cover a total of about 100 pesticides including the classes: benzoylphenylureas,\(^{(49)}\) benzimidazoles,\(^{(50)}\) conazoles,\(^{(48)}\) carbamates,\(^{(51)}\) and phenylureas.\(^{(48)}\) Study and validation demonstrated\(^{(48)}\) that the efficient and miniaturized extraction (see Figure 10) used for the GC MRMs\(^{(1)}\) was also applicable for extraction of the polar pesticides. Each SPE/LC procedure was fully automated by means of a commercially available SPE apparatus (ASPEC). Concerning carbamates and phenylureas more information about method performance will be given in section 3.2. The separation of benzimidazoles (carbendazim/thiabendazole) and conazoles (imazalil/prochloraz) were performed on a 150 × 8 mm ID column packed with Superspher 60 RP-8 and a 250 × 4.6 mm ID column packed with Inertsil ODS-3, respectively. The mobile phase consisted of 70% ACN (conazoles) or methanol (benzimidazoles) in phosphate buffer pH 7. The SPE cleanup on the diol cartridges appeared to be very effective. It allowed UV detection at 210 nm of imazalil and prochloraz at a level of 0.1 mg kg\(^{-1}\) without the occurrence of interfering peaks from the various types of blank commodities (foodstuffs) investigated. Also for carbachlor and thiabendazole this cleanup provided high selectivity.\(^{(50)}\)

Benzoylphenylureas were separated on a 150 × 3 mm ID column packed with 4 µm Superspher 60 RP-8 and using an ACN–water gradient of 15 min at flow of 0.5 mL min\(^{-1}\). The good performance of the LC method is shown in Figure 11 for the analysis of an extract of a green pepper spiked with analytes at a level of 0.1 mg kg\(^{-1}\). Additional confirmation was obtained with DAD and unambiguous identification was done with GC/MS using either electron impact (EI) and/or chemical ionization (CI) mode. The limit of determination of the method was 20 µg kg\(^{-1}\) for each compound. All LC methods allowed the determination of these pesticides far below the MRLs.

### 2.6 Coupled Column/Ultraviolet Methods

An overview of on-line LC/LC/UV methods\(^{(9–11,52–57)}\) for the trace analysis of various pesticides and related compounds in water samples is made in Table 3. The simplicity and effectiveness of the LC/LC/UV analyzer (see Figure 5) provides selective methods with a high sample throughput (run times of about 10 min). As discussed above and illustrated by the data given in Tables 2 and 3 the LVI in case of very polar analytes is limited. Hence, for compounds like CAAL and ETU, LVI is limited to 0.2–0.5 mL yielding LODs in the range of 1 µg L\(^{-1}\). By the use of relatively simple manual concentration steps the LODs can be lowered to the EC drinking-water limit of 0.1 µg L\(^{-1}\).\(^{(52–54)}\) For compounds with sufficient C\(_{18}\) retention and UV detection (see Table 2) LODs of 0.1 µg L\(^{-1}\) can be obtained employing sample injections below 8 mL (see data of Tables 2 and 3). Figure 12 clearly demonstrates the performance of LC/LC/UV analysis: the trace analysis of isoproturon in surface water in less than 8 min. It also shows the significant improvement in selectivity of LC/LC in comparison to the use of two coupled C\(_{18}\) columns without column switching, a phenomena also encountered in ion chromatography.\(^{(58)}\)

A rather unexpected matrix-dependent retention time was reported in the simultaneous determination of bromacil and in diuron employing LVI LC/LC/UV,\(^{(55)}\) Investigating LC grade, drinking and surface water differences in retention times of about 1 min were observed indicating that one must consider this effect in LC/LC method development. Nevertheless, the LC/LC method is distinctly more efficient in comparison to the method previously in use, which employed a laborious sample pretreatment step.\(^{(59)}\)
HPLC METHODS IN PESTICIDE RESIDUE ANALYSIS

Figure 10 Scheme of MRMs as applied for the determination of polar pesticides in fruits and vegetables and according to refs. 48–51.

Figure 11 RPLC/UV (260 nm) of an extract of a green pepper sample spiked with benzoylphenylurea pesticides at a level of 0.1 mg kg\(^{-1}\). Sample pretreatment is given in Figure 10. LC conditions: 150 × 3 mm ID 4 µm Super-spher 60 RP-8 column with an ACN–water gradient elution from 25 to 50% in 15 min. Peaks: 1. diflubenzuron; 2. triflumuron; 3. triflubenzuron; 4. hexaflumuron; 5. lufenuron; 6. flufenoxuron; 7. chlorfluazuron.

The SRMs shown in Table 3 make use of small transfer volumes, typically 0.2–0.9 mL, in order to enhance selectivity. Although expected, the MRMs requiring larger transfer volumes\(^{57}\) did not offer sufficient selectivity. This emphasizes that in LC/LC the performance of an efficient cleanup on C-1, which means the removal of S1, is a predominant selectivity parameter for this type of analysis. The performance of on-line multiresidue analysis of triazines in surface water at a level of 0.4 µg L\(^{-1}\) is given Figure 13.

The examples discussed above clearly demonstrate the main advantage of on-line LC/LC/UV: the fast screening of a wide variety of compounds in environmental water samples. For analytes with sufficient UV absorption/selectivity (\(\varepsilon \) and \(\lambda \) values of more than 15 000 L mol\(^{-1}\) cm\(^{-1}\) and 220 nm, respectively) and C\(_{18}\) retention (\(k > 50\), in pure water) LODs in the range of 0.1 µg L\(^{-1}\) are feasible. However, owing to its maximum

a Type of columns: A, 50 × 4.6 mm ID packed with 3µm Microspher C₁₈; B, 100 × 4.6 mm ID packed with 3µm Microspher C₁₈; C, 150 × 4.6 mm ID packed with 5µm Hypersil ODS; D, 30 × 4.6 mm ID packed with 5µm Spherisorb ODS-2; E, 125 × 4.6 mm ID packed with 5µm Spherisorb ODS-2.

b 0.1% phosphoric acid in water.
c Containing 0.2% of ammonia.

A comparison between LVI on-line LC/LC/UV and off-line SPE combined with LC/LC/UV for the trace analyses of triazines and some metabolites in water samples showed similar results: on-line LC/LC/UV favors speed of analysis while a simple preceding off-line SPE step provides LODs in the range of 0.02–0.05 µg L⁻¹.⁶⁷ Another comparative study included the use of hydrophobic on-line SPE/LC (PC/LC).⁶⁸ It appeared that in comparison to LVI LC/LC/UV and off-line SPE combined with LC/LC/UV, PC/LC favors sensitivity and speed of analysis at low levels (<0.1 µg L⁻¹) but selectivity is considerably less.
Off-line SPE and LC/LC/UV were successfully applied in an interlaboratory study involving the determination of phenylurea herbicides spiked at levels of about 0.1 \( \mu \text{g L}^{-1} \) to drinking water, groundwater and surface water. The SPE procedure involved the sampling of 250 mL of water on a 500 mg C\(_{18}\) SPE cartridge preconditioned before use with 3 mL of methanol, 3 mL of acetone, 3 mL of methanol and 6 mL of LC-grade water. After sample loading, the cartridges were dried by passing air for 30 min and the analytes were eluted with 2 mL of acetone. An aliquot of the acetone corresponding to 125 mL of sample was transferred in a tube and evaporated to dryness with a gentle stream of nitrogen. The residue was redissolved by adding first 0.20 mL of ACN followed by 1.8 mL of LC-grade water. The LC/LC/UV analysis displayed in

Figure 12 LC/LC/UV (244 nm) of surface water sample spiked with isoproturon at a level of 0.5 \( \mu \text{g L}^{-1} \). LC/LC conditions, see Table 3. A, chromatogram obtained with column switching; B, chromatogram using the two columns in series without column switching.

Figure 13 LC/LC/UV (233 nm) of a surface water sample spiked with triazine herbicides at a level of 0.4 \( \mu \text{g L}^{-1} \). LC conditions, see Table 3. Peaks: (1) simazine, (2) atrazine, (3) terbutylazine, (4) terbutryn.

Figure 14 Off-line SPE and LC/LC/UV (244 nm) of an SPE extract of a surface water containing (1) monuron (0.18 \( \mu \text{g L}^{-1} \)), (2) monolinuron (0.70 \( \mu \text{g L}^{-1} \)) and (3) diuron (0.20 \( \mu \text{g L}^{-1} \)). LC conditions: C-1, 3 \( \mu \text{m Microspher C}_18\) (50 x 4.6 mm ID); C-2, 3\( \mu \text{m Microsphere C}_18\) (100 x 4.6 mm ID); M-1 and M-2, methanol–water (55:45, v/v) both at 1 mL min\(^{-1}\); injection 150\( \mu \text{L}\) of SPE extract (procedure, see Text); cleanup volume, 1.3 mL; transfer volume, 3.4 mL.

Figure 14 of a surface water sample containing monuron, monolinuron and diuron at a level of 0.18, 0.70 and 0.20 \( \mu \text{g L}^{-1} \), respectively nicely demonstrates the good performance of this approach on both selectivity and sensitivity.

A new development in the determination of acidic compounds in environmental samples is the beneficial
The RPLC/UV analysis of acidic pesticides (small molecules) in environmental samples is usually severely hampered by co-extracted humic substances (large molecules) which show up as a broad hump in the chromatogram. Indeed, improved chromatographic performance was obtained for determination of a group of chlorophenoxy acid herbicides in environmental waters by SPE/LC/UV (220 nm) employing a PC packed with ISRP 5 μm GFF-II, RAM. Unfortunately, the ISRP PCs of different batches showed poor reproducibility in the required retention of the analytes, hence providing insufficient selectivity.

Improved results were obtained when employing RAM columns in the LC/LC mode, that is, using analytical RAM columns. In a recent comprehensive study the applicability of several commercially available analytical RAM columns in LC/LC/UV for the trace analysis of acidic herbicides in water samples was investigated. Different LC configurations were studied including the single RAM column mode and column switching LC/LC employing one RAM column in combination with an analytical C18 column or two RAM columns. Involving a group of acidic herbicides representing different chemical families, both the SRM and MRM approach were tested applying SPE C18 extracts of reference water samples spiked with the analyte(s) at the 0.5–1.0 μg L⁻¹ level and containing dissolved organic carbon (DOC) between 3 and 12 mg L⁻¹. Information on the type of RAM of columns studied and adequate coupled column conditions is given in Table 4.

As regards SRM the use of one analytical RAM or two different types of RAM columns sufficiently improved the resolution between the analyte and the interference of humic acids to perform trace analysis in the SPE extracts with a preceding cleanup. Figure 16 demonstrates the effectiveness of the LC/LC approach involving an ISRP column as the C-1 for the single residue analysis of the polar metsulfuron-methyl herbicide at a level of 1 μg L⁻¹.

c Modifier content in mobile phase consisting of methanol–0.03 M phosphate, pH 2.4 (v/v).

Figure 15 Schematic presentation of retention mechanism of the 5 μm GFF-II ISRP material. Outer layer, glycine (polar); Inner layer, glycine–phenylalanine (nonpolar).
Both ISRP and Hisep RAM columns provide a very efficient preseparation between acidic analytes and humic interferences. However, these columns showed, in comparison to C18, a different separation mechanism which resulted in a reversed elution order and a significant increase of band broadening for some of the analytes. This feature can be disadvantageous in the MRM of pesticides of various classes. The good performance of LC/LC/UV involving the C18/SPS analytical column combination is demonstrated in Figure 17 showing the simultaneous trace analysis of a group of acidic pesticides from different classes in water containing a DOC content of 6 mg L\(^{-1}\) and spiked with the analytes at the 0.5–1.0 µgL\(^{-1}\) level.

In comparison to water, soil will contain more interferences. Hence, cleanup will be even more important in the analysis of soil extracts, therefore LC/LC is an attractive technique to perform efficient on-line cleanup. In a monitoring program aimed at the occurrence of the more persistent pesticides, two LC/LC/UV based screening methods were developed for the analysis of the pesticides pencycuron and fenpropimorf in soil.\(^9\) A simple sample extraction/concentration procedure was applied employing an overnight standing of soil in ACN followed by a filtration and a concentration step. The gain in selectivity provided by LC/LC is demonstrated in Figure 18 which shows the RPLC/UV (215 nm) analysis of soil spiked with 50 µg kg\(^{-1}\) of fenpropimorf.

As has been demonstrated recently, the use of an analytical RAM column in LC/LC/UV is also favorable for the separation of acidic pesticides.
for the analysis of acidic compounds in soils. For the screening of MCPP in soils a LC/LC/UV method has been developed using a 50 × 4.6 mm ID RAM column packed with 5 µm ISRP (Pinkerton) as C-1. It appeared that in comparison to an analytical C18 column the ISRP µ packed with 5 has been developed using a 50 has substantially improved the separation between acidic analyte and co-extracted humic substances. Under the selected LC/LC conditions uncleaned soil extracts obtained after a rapid extraction/concentration procedure were directly processed with LC/LC/UV (220 nm) allowing the determination of MCPP in soils to a level of 0.02 mg kg⁻¹.

3 REVERSED-PHASE LIQUID CHROMATOGRAPHY WITH FLUORESCENCE DETECTION

3.1 Liquid Chromatography/Fluorescence Detection Methods

FD measuring the emitted light after the absorption of light by a compound both at a specific wavelength is very selective and sensitive. Compounds that normally undergo fluorescence can have a 100–1000-fold increase in sensitivity over UV detection, making it attractive to be used in pesticide residue analyses. Unfortunately, very few pesticides have a favorable fluorophore. A good example is the antiparasitic agent ivermectin for which very selective and sensitive. Compounds that normally undergo fluorescence can have a 100–1000-fold increase in sensitivity over UV detection, making it attractive to be used in pesticide residue analyses. Unfortunately, very few pesticides have a favorable fluorophore. A good example is the antiparasitic agent ivermectin for which very selective and sensitive. Compounds that normally undergo fluorescence can have a 100–1000-fold increase in sensitivity over UV detection, making it attractive to be used in pesticide residue analyses. Unfortunately, very few pesticides have a favorable fluorophore. A good example is the antiparasitic agent ivermectin for which very selective and sensitive.

Pre- or postcolumn derivatization techniques have substantially extended the use of FD in this field of analysis. The most widely adopted technique is the postcolumn reactor for the detection of N-methylcarbamates. After the RPLC separation a two-postcolumn reaction system provides hydrolyses of analytes to methylamine and reaction of this product with o-phthalaldehyde (OPA) for the formation of a highly fluorescent derivative. This approach has been introduced by Moye et al. and further modified and optimized by Krause providing robust, selective and sensitive methods for the multiresidue determination of N-methylcarbamates in crop samples. The SPE cleanup of the organic extracts on a cartridge packed with bonded aminopropyl-silica and carried out in the normal-phase mode appeared to be effective and rapid. The robustness of the OPA postcolumn reaction detection is also emphasized by forming the basis of the United States Environmental Protection Agency (USEPA) Method 531.1 for the determination of N-methylcarbamate pesticides in environmental water samples.

Optimization of hydrolysis by means of a solid-phase reactor consisting of a column packed with anion-exchange material distinctly simplified the post-column derivatization technique and extended the analysis to 22 carbamate pesticides and 10 metabolites in crops with LODs in the range of 1–10 µg kg⁻¹. The same approach including off-line SPE of 50 mL of sample on cartridges packed with 500 mg of low-carbon C18-bonded silica (C18/OH) for trace enrichment provided a method for determination of 20 carbamates and 12 metabolites in surface water at the low ng L⁻¹ level; a 250 × 4 mm ID column packed with 4 µm Superspher 60 RP-8 was used for the separation of carbamates and metabolites using ACN–water gradient of 30 min at flow of 1 mL min⁻¹.

Another approach to hydrolysis of carbamates and N-containing pesticides such as phenylureas prior to derivatization with OPA was introduced by Miles and Moye who employed a photolytic reactor consisting of a UV lamp inserted in the center of a woven coil of Teflon tubing. The postcolumn on-line photochemical reactor in combination with fluorescence, electrochemical or conductivity detection provided MRMs for the assay of over 100 pesticides in the groundwater samples. PC derivatization using 1-methylimidazole and TFA was successfully applied for the LC/FD determination of the large molecular compound abamectin in forest matrices including water, soils and foliage. Sample pretreatment consisted of an extraction with dichloromethane and cleanup with Florisil column chromatography. Limits of quantification were 0.2 µg kg⁻¹ and 0.01 µg L⁻¹ for solid and water samples respectively.

3.2 Solid-phase Extraction/Liquid Chromatography/Fluorescence Detection Methods

Hiemstra and Kok transformed the method involving off-line SPE into a completely automated method for the determination of carbamates in water. The study included the testing of two different, commercially available, automated trace enrichment devices (Prospekt and OSP-2). Both trace enrichment systems showed a good method performance and with small sampling volumes of 3 mL (OSP-2 system) or 5 mL (Prospekt system) detection limits (DLs) of the carbamates and their metabolites for surface water were between 30 and 50 ng L⁻¹; the sample throughput was about 30 samples per 24 h.

The same degree of automation was obtained for the processing of crop extracts by means of an automated SPE cleanup apparatus. This system (ASPEC), performs cleanup on a SPE amino-bonded silica column and, after a solvent switch, the injection of part of the extract into the LC carbamate analysis system (see Figure 10). The good results on recovery and repeatability from 13 carbamates and 12 metabolites on 12 different types of
food products and the registration of control samples in Shewhart charts during several years of routine analysis have clearly demonstrated the good performance of this approach.\(^{(48,51)}\)

In the analysis of \(N\)-methyl carbamates employing LC, hydrolysis, OPA derivatization and FD, on-line and off-line cleanup of vegetable extracts has been carried out by using activated carbon membranes.\(^{(82)}\) The highly retentive property of the SPED material allowed direct injection of 20 \(\mu\)L of toluene-modified ACN extract and provided an effective retention of sample interferences. The method tested on green peppers spiked at a level of 0.25 \(\text{mg kg}^{-1}\) with 10 carbamates provided recoveries at levels between 56–93% and 87–99% for the on-line and off-line SPED cleanup, respectively.

The instrumental analysis displayed in Figure 19 of an uncleaned extract of a carrot sample fortified with 0.1 \(\text{mg kg}^{-1}\) of phenylurea herbicides shows the good performance and the high selectivity/sensitivity of this approach; if necessary, an automated SPE sample cleanup can be included in the method (see Figure 10).

![Figure 19](image)

**Figure 19** RPLC with FD (ex: 340 nm, em: 455 nm) with reaction detection involving post-column photolysis and derivatization with OPA of an uncleaned extract of a carrot sample spiked with phenylurea herbicides at a level of 0.1 \(\text{mg kg}^{-1}\). Sample pretreatment is given in Figure 10. LC conditions: 250 \(\times\) 4.6 mm ID 4 \(\mu\)m Superspher 60 RP-8 column with an ACN–water linear gradient elution from 35 to 60% of modifier in 30 min at flow of 1 \(\text{mL min}^{-1}\); photolysis, knitted reaction coil (250 \(\times\) 5 mm) and irradiation with UV at 254 nm. Peaks: 1. fenuron; 2. metoxuron; 3. monuron; 4. chlorotoluron; 5. fluometuron; 6. isoproturon; 7. dinexuron; 8. metobromuron; 9. buturon; 10. linuron; 11. chlorbromuron; 12. neburon.

### 3.3 Coupled Column/Fluorescence Detection Methods

The LC/LC/FD technique has been successfully applied for the efficient determination of phosphinic acid herbicides glufosinate and glyphosate and glyphosate’s metabolite amino methyl phosphonic acid (AMPA).\(^{(83–85)}\) These herbicides are widely used in agriculture as nonselective contact herbicides. Because of their high polarity, amphoteric properties and poor detectability, methodology to determine these compounds at trace levels requires a large effort in sample preparation steps such as extraction, concentration, derivatization and cleanup. A study on the determination of glufosinate in environmental water samples\(^{(83)}\) demonstrated that the combination of PC derivatization with 9-fluorenylmethylchloroformate (FMOC-Cl) and LC/LC/FD considerably improves the sample throughput. The method uses a C\(_{18}\) column coupled to an ion-exchange amino column with a mobile phase of ACN–0.05 M phosphate buffer, pH 5.5 (35 : 65, v/v) for both columns.

It must be emphasized that the cleanup performance here is obtained in a reversed way. Instead of removing an excess of early eluting interferences (S1, see also Figures 3 and 5) one advantageously makes use of the amphoteric property of FMOC–glyphosate. In the LC/LC approach the mobile phase ionizes the analyte which will result in little \(C_{18}\) retention on C-1 and an adequate retention on C-2. The efficient cleanup is obtained by transferring an almost unretained small-analyte-containing fraction from C-1 to C-2. All interferences with more \(C_{18}\) retention, e.g. the excess of FMOC-OH, are retained on C-1 and sent to waste by the rinsing mobile phase during the separation of the analyte on C-2.

It was established that LVI could be achieved by reducing the percentage of modifier (40% ACN is required for adequate derivatization with FMOC) with an aqueous borate buffer solution before injection. For example, a four-fold dilution step allowed the injection of 2.0 \(\text{mL}\) of sample without significant band broadening of the polar FMOC–glufosinate during injection on the C\(_{18}\) column (C-1). However, in the mobile phase (M-1) the \(C_{18}\) retention of an ionic FMOC-phosphoric acid is very little and the analyte will elute then almost as an unretained compound. Hence, shortly after LVI the analyte will be transferred to the amino column (C-2) in a relatively small volume (approx. 250 \(\mu\)L) In this way an efficient preseparation between the large excess of the FMOC reagent and the FMOC analyte is realized.

The usefulness of this approach was also investigated for the determination of glyphosate and its main metabolite AMPA in environmental water samples.\(^{(84)}\) It appeared that for glyphosate an eight-fold dilution step was necessary to avoid excessive band broadening of...
glyphosate–FMOC during LVI. Glufosinate, glyphosate and AMPA could indeed be assayed simultaneously in aqueous samples at a level of 1 µg L⁻¹ with a high sample throughput. An example of this approach is given in Figure 20, showing the LC/LC/FD analysis of surface water sample spiked with three analytes at the level of 4 µg L⁻¹.

SRMs focused on the analysis of one analyte applying very accurately adjusted volumes for dilution, cleanup and transfer allowed the determination down to the 0.1 µg L⁻¹ level.

Employing SRMs, glufosinate, glyphosate and AMPA were successfully recovered from water samples at 0.5–10 µg L⁻¹ level fortification levels, with a sample throughput of at least 40 samples per day.⁸⁴

The same approach has been applied for the determination of glyphosate and AMPA in soil samples.⁸⁵ After extraction in alkaline media an aliquot of the extract is neutralized and processed with the procedures mentioned above. Depending on the type of soil, whether it had high or low clay content and organic matter, limits of determination are 100 and 10 µg kg⁻¹, respectively for both analytes.

4 REVERSED-PHASE LIQUID CHROMATOGRAPHY WITH MASS SPECTROMETRIC DETECTION

4.1 General Aspects

The possibility of performing determination and unambiguous identification of polar pesticides simultaneously makes LC with MS detection an attractive and fast growing technique in the field of PRA. In comparison to the usually applied universal UV or photodiode array detectors, confirmation analysis with MS detection is usually not encountered with problems like (almost) identical UV spectra of compounds of a same class (e.g. phenylureas) or compounds lacking a chromophore (e.g. phosphonic acids). This results in liquid chromatography/mass spectrometry (LC/MS) having a high potential for analyzing a broad spectrum of pesticides and, hence, potentially a high productivity in multi-residue analyses.

The principles of the various LC/MS interfaces and the various types of interfaces as applied for the determination of polar pesticides have been described.⁸⁶ Until the mid-1990s most applications involved thermospray (TSP) or particle beam (PB) interfaces.⁸⁶ The advantage of obtaining EI spectra when using the PB interface makes liquid chromatography/particle beam mass spectrometry (LC/PBMS) very powerful in the detection and determination of polar pesticides. Several LC/PBMS based MRMs have been developed for the trace analysis of triazines, phenylureas and/or carbamates in water samples employing off-line or on-line solid extraction procedures. The possibility to obtain positive and/or negative CI spectra and to compare data to GC/MS data bases is an important feature of this technique, but evidently concerns only GC-amenable pesticides such as triazines and organophosphorus compounds.⁹²

In comparison to the PB interface, liquid chromatography/thermospray mass spectrometry (LC/TSPMS) is more compatible with conventional HPLC-system mobile phases, including solvent additives, and offers in most cases higher sensitivity. Based on studies investigating optimal TSP ionization conditions for pesticides, several LC/TSPMS MRMs including the determination of numerous pesticides of different classes, e.g. phenylureas, carbamates, phenoxy acids, triazines and oxime fungicides etc. in aqueous environmental samples have been developed.⁹⁶–⁹⁸
Unfortunately, TSP shows a number of experimental problems such as highly variable compound-dependent responses, the need for a critical control of relevant temperatures during analysis, thermal breakdown of labile analytes and the lack of structurally informative mass spectra. The last problem can be overcome by using liquid chromatography/tandem mass spectrometry (LC/MS/MS); identification can be achieved by using daughter ion tandem mass spectrometry (MS/MS) scans and collisionally induced dissociation (CID), most commonly on a triple quadrupole instrument. However, in comparison to LC/MS the instrumental cost of MS/MS systems are distinctly higher.

An important limitation encountered in both thermospray mass spectrometry (TSPMS) and particle beam mass spectrometry (PBMS) is the significant variation in sensitivity between the different classes of compounds or even for compounds from the same class. As regards this aspect, atmospheric pressure ionization (API) is most promising in combining high sensitivity and improved ionization stability by solving the problem of vaporized solvent entering the vacuum system of the mass spectrometer. API includes a group of interfaces usually addressed as electrospray (ES), ionspray (IS) and atmospheric pressure chemical ionization (APCI), which is the most flexible technique regarding conventional LC flow rates.

At present API interfaces are the most commonly used in LC/MS for target and nontarget analysis of pesticides from various matrices and the various mode applied in this field of analysis will discussed in more detail below.

4.2 Liquid Chromatography/Mass Spectrometry Methods

Volmer et al.\(^{(99)}\) evaluated the use of LC/ESMS for multiresidue determination and confirmation of a large number of pesticides such as triazines, carbamates, phenyl- and sulfonylureas. Performing separation of analytes on 5µm C\(_{18}\) column (150 x 3.2 mm ID) with a methanol–water gradient (20–95% methanol over 45 min) at 0.6 mL min\(^{-1}\), post-column flow addition (0.4% formic acid in methanol, at 0.2 mL min\(^{-1}\)) and by means of splitting a 150µL min\(^{-1}\) flow to the ESMS positive ionization (PI mode), time-scheduled single ion monitoring (SIM) yielded sensitive detection of most pesticides at the very low picogram level. Di Corcia et al.\(^{(100)}\) developed a sensitive and specific method for the ultratrace analysis of atrazine and its major six metabolites in environmental water samples. The method makes use of SPE on cartridges packed with GCB followed by LC/ESMS. LC separation was carried on 5µm C\(_{18}\) column (250 x 4.6 mm ID) with a gradient elution of methanol–water (both solvents contained 10\(^{-5}\) mol L\(^{-1}\) of formic acid) going from 0 to 84% methanol in 36 min. The flow rate of the mobile phase was 1 mL min\(^{-1}\), and 40µL of the column effluent was diverted to the ES source. Employing extraction volumes of 1 and 4 L of sample (river, ground- and drinking water) LODs of 3 ng L\(^{-1}\) were obtained (two-ion SIM acquisition) with a reproducibility of 2–7% and recoveries above 80%.

More or less the same approach concerning sample pretreatment and instrumental analysis was successfully applied by D’Ascenzo and co-workers\(^{(101)}\) for the determination of five imidazolinone herbicides in various drinking water samples providing LODs of 2–5 ng L\(^{-1}\).

The same group\(^{(102)}\) developed an MRM for determination of 15 acidic herbicides (7 sulfonylureas, 4 imidazolinones, 4 aryloxyphenoxycarboxylic acids) in water by LC/ESMS in PI mode. A similar pretreatment procedure as mentioned above was used: passing of 2 L of ground-water and 4 L of drinking water samples, respectively, through a 0.5 g GCB extraction cartridge. A conventional 4.6 mm ID column operating with a methanol–water mobile phase (both solvents contained 10 mmol L\(^{-1}\) formic acid) at 1 mL min\(^{-1}\) was used to separate the analytes; from the column effluent, 200 µL min\(^{-1}\) were split to the ESI source. The very good performance of this approach is illustrated in Figure 21 showing total ion current (TIC) and time scheduled SIM chromatograms of the LC/ESMS analysis of a drinking water sample spiked with analytes at a level 25 ng L\(^{-1}\) each. The LODs calculated in SIM mode for drinking water were in the range of 0.5–4 ng L\(^{-1}\). This method has also been applied to real groundwater samples in which imazamethabenz, imazathabenz-methyl, haloxynfop, fluazifop and chlorosulfuron were found in concentrations ranging from 10 to 100 ng L\(^{-1}\). Employing slightly different LC/ESMS conditions and SPE concentration on Porapak Rdx cartridges (Waters) comparable results were obtained for a group of 22 acidic pesticides of different classes when using SIM in negative ionization (NI) mode.\(^{(103)}\)

The viability of off-line sampling of water samples on GCB cartridges and LC/ESMS towards multiresidue analysis of pesticides in environmental water samples is also illustrated by Crescenzi et al.\(^{(103)}\) They developed a method for the determination of 45 base/neutral pesticides (carbamates, triazines, imidazole, phenylureas, anilides, triazoles, pyridazones) having a broad range in polarity. ESMS detection was optimized by adopting in-glass distilled methanol and 10µmol L\(^{-1}\) TFA in water as mobile-phase constituents. For drinking water, LODs ranged between 1 (atrazine) and 9 (butoxycoarboxim) ng L\(^{-1}\) from TIC chromatograms and were for most pesticides about 10 times lower when using SIM. The repeatability of the method of less then 10% for the analysis of an extract (n = 7) of a surface water sample spiked with the analytes at a level of 200 ng L\(^{-1}\), emphasizes the ruggedness of the ESMS arrangement.
The combination of a SPE cleanup on a GCB cartridge and LC/ESMS appeared also viable for the determination of 12 carbamate insecticides in fruits and vegetables to levels below 1 µg kg⁻¹ of crop.  

An intra- and interclass comparison of sensitivity, ionization and fragmentation for the determination of 17 pesticides in 5 chemical classes (triazines, phenylureas, organophosphorus, miscellaneous) in water with liquid chromatography/atmospheric pressure chemical ionization mass spectrometry (LC/APCIMS) was investigated by Doerge and Bajic. Performing LC separation on a short C₁₈ column (30 × 4.6 mm ID) with ACN–water mixtures at a flow rate of 0.5 mL min⁻¹ as the mobile phase the spectra obtained from most compounds consisted solely of [M + H]⁺ in positive ion mode. Low nanogram LODs were observed for all compounds in scan mode and these were reduced to picogram levels by using SIM mode. For these diverse chemical classes variations in LODs were obtained of ca. 10-fold and 100-fold for scan and SIM mode respectively.

Barnes et al. developed LC/APCIMS based methods for the determination of various pesticides in different types of foodstuffs. Diflubenzuron and clofentezine were determined in fruits employing a liquid organic solvent extraction and high-performance gel permeation chromatography (HPGPC) cleanup as sample pretreatment. Applying RPLC with methanol–water (80:20; v/v) as the mobile phase (1 mL min⁻¹) and atmospheric pressure chemical ionization mass spectrometry (APCIMS) in the PI mode, LODs were about 0.01 mg kg⁻¹. For the multiresidue analysis of 10 various pesticides (6 carbamates, thiabendazole, carbendazim, clofentezine, diflubenzuron) in fruits samples were extracted with ethyl acetate. After solvent evaporation part of the diluted extract was directly processed with LC/APCIMS using PI/NI mode during each acquisition, which provided LODs in the range of 0.002–0.03 mg kg⁻¹ in the crop. The LODs obtained in the LC/APCIMS methods clearly met the required MRLs for these compounds in foodstuffs. Despite the favorable features...
it was observed that sensitivity is both compound- and matrix-dependent and will require next to solvent-based standards (check on column/instrument performance) additional calibration with matrix-matched standards.\(^{(107)}\)

API applied in the LC/MS methods discussed above is a soft ionization technique that predominantly produces the protonated \((M + H)^+\) or deprotonated \((M – H)^-\) molecular ions in positive or negative mode, respectively. Increase in compound identification can be obtained by MS/MS based on detection of product ion(s) (daughter ions) formed by CID of the initially formed (de)protonated molecular ion (parent ion). For the determination of 22 acidic pesticides in water a comparison of LC/ES method performance by single MS and MS/MS was made employing a triple quadrupole instrument.\(^{(108)}\) Despite a three-to four-fold decrease of the signal-to-noise ratio of analytes, the significant improvement in selectivity of MS/MS is clearly demonstrated in Figure 22 showing LC/ESMS analysis of a real-life groundwater sample containing three phenoxy acids at levels of about 10 ng L\(^{-1}\).

The impressive improvement in selectivity of MS/MS was also demonstrated for the determination of imidazoline herbicides in soils.\(^{(109)}\) This new class of low-use-rate herbicides must be monitored at low parts per billion levels, which could be achieved by using liquid chromatography/electrospray tandem mass spectrometry (LC/ESMS/MS).

### 4.3 On-line Liquid Chromatography/Mass Spectrometry Methods

Because of the possibility of automation, on-line procedures allow large screening and monitoring of environmental water samples. Therefore, besides or complementary to automated SPE/LC/UV/DAD systems the use of atmospheric pressure ionization mass spectrometry (APIMS) detection becomes more important in this field of analysis. The determination of 8 various types of acidic herbicides in environmental water was performed by automated on-line SPE on C\(_{18}\) cartridges and LC/MS using pneumatically assisted (or high flow) electrospray (PAES) for ionization in the NI mode.\(^{(110)}\) The procedure required only 50 mL of water with LODs ranging between 10 and 30 ng L\(^{-1}\) including the determination of the two major metabolites of bentazone.

SPE/LC (100 mL of sample) coupled to APCIMS, pneumatically assisted/electrospray mass spectrometry (PA/ESMS) and MS/MS detection was used for the trace analysis of a group of neutral pesticides (carbamates, phenylureas, triazines and organophosphorus) in water samples.\(^{(111)}\) The interfaces provided comparable LODs for 15 pesticides (out of 17) in drinking water of 0.007–3 \(\mu\)g L\(^{-1}\) and 0.1–200 ng L\(^{-1}\) in TIC and SIM.

---

**Figure 22** LC/ESMS analyses of a SPE extract of a real-life groundwater sample containing chlorophenoxy acid herbicides at a level of about 0.010 \(\mu\)g L\(^{-1}\). The sample was analyzed using (a) single MS in SIM and by (b) MS/MS in selected reaction monitoring mode. Peaks: (1) MCPA, (2) 2,4-D, (3) 2,4-DP. (Reprinted from Koppen and Spliid, ‘Determination of Acidic Herbicides Using Liquid Chromatography with Pneumatically Assisted Electrospray Ionization Mass Spectrometry and Tandem Mass Spectrometry Determination’, *J. Chromatogr. A.*, 803, 157–168. Copyright © 1998 with permission from Elsevier Science.)
mode, respectively, with an analysis time of 65 min. NI operation was found to be less sensitive for the majority of compounds tested (73 in total). Both ionization techniques gave similar product ion spectra from protonated molecules and a MS/MS library was built for searching more than 60 pesticides and successfully applied for searching product-ion spectra at low levels (10 ng L$^{-1}$) in tap water.

The simultaneous analysis of a smaller and less heterogeneous group of pesticides, usually enhances sensitivity in LC/MS. A nice example is given in the study by Baltussen et al.$^{(112)}$ A sample volume of 10 mL appeared to be sufficient for the on-line LC/MS determination of five phenylurea herbicides in river water to a level of 10 ng L$^{-1}$.

High sensitivity/selectivity was obtained by on-line immunosorbent phase extraction and LC/APCIMS (PI mode) for the analysis of 8 triazine and 6 phenylurea herbicides in environmental samples.$^{(113)}$ Sample volumes of 20 mL of groundwater provided LODs in the range 1–5 ng L$^{-1}$ For obvious reasons such as removal of early eluting interferences and protection of analytical column, on-line methods usually make use of column-switching (see above) for the trace enrichment of analytes on a SPE column (PC).

For the reduction of expensive measurement time of the LC/MS system the use of a single short column (SSC) for both trace enrichment and separation in combination with selective MS/MS detection is a powerful approach. The compromise between the minimum time of analysis and the minimum required chromatographic separation for a given application is determined by the efficiency of the column (total number of plates, $n$) which in turn will depend on the dimensions of the column and efficiency of the packing material. In fact, suitable conditions for sorption and desorption will always include a washing step (removal of inorganic salts) prior to elution, and minimum required separation between analyte(s) and solvent front in order to avoid the unstable ionization conditions caused by the rapidly changing elution solvent composition.

The viability of the SSC approach is shown by a number of methods involving the rapid determination of organic pollutants in water.$^{(114-116)}$ The first report on the SSC approach involved the use of a home-packed (5–8 $\mu$m C$_{18}$ or 10–15 $\mu$m PLRP-S material) 10 $\times$ 2 mm ID column in combination with thermospray/tandem mass spectrometry (TSPMS/MS) for the on-line determination of triazines in surface water.$^{(114)}$ Unfortunately, stability-system problems related to the reproducibility and stability of the experimental column packings did not provide LODs below 10 $\mu$g L$^{-1}$. Improved results were obtained when using a 20 $\times$ 4.6 mm ID column high-pressure packed with 5 $\mu$m C$_{18}$ combined with atmospheric pressure chemical ionization tandem mass spectrometry (APCIMS/MS).$^{(115)}$ For the set of 15 various pesticides analyzed before with SPE/LC, the SSC approach involving the processing of sample volumes as small as 15 mL resulted in LODs between 0.03 and 5 $\mu$g L$^{-1}$ in full-scan mode and between 2 and 750 ng L$^{-1}$ by SIM, both recorded in the positive ion mode. Further optimization of the use of SSC with APCIMS/MS involving ion-trap MS/MS instead of triple quadrupole MS/MS allowed the trace analysis of six triazines in less than 20 min by taking only 4 mL of sample and, hence, providing a high sample throughput. Unfortunately, sensitivity was not sufficient for the 8 phenylurea herbicides tested; this was probably caused by several current instrumental problems. SSC in the instrumental set-up including both diode-array UV and MS detection is an efficient approach in guarding microorganic pollution of surface waters. In these types of samples usually few or no microcontaminants are present allowing a degree of selectivity to be sacrificed by using less separation power in order to obtain a cost-effective procedure.$^{(116)}$

5 LIQUID CHROMATOGRAPHY SAMPLE PRETREATMENT METHODS PRIOR TO GAS CHROMATOGRAPHY

The availability of techniques, nowadays, to perform large-volume introduction GC,$^{(117)}$ has made the combination of LC and GC more accessible. As a result, one can easily combine the advantageous features of LC such as on-line trace enrichment and/or cleanup with the high separation power and selectivity/sensitivity of capillary GC.

Based on the type of sample/extract and the type of mobile phase, that is an aqueous solvent or an organic solvent, one can discriminate two different modes in LC methods used in combination with GC.

The LC mode employing organic solvents is focused on the efficient cleanup between macromolecules such as fatty substances (triglycerides) or plant material (chlorophyllic) and pesticides. In these types of separations GPC and NPLC are used because of their high degree of automation. The other LC-mode is based on coupling SPE columns to capillary GC providing on-line analysis of pesticides in environmental water samples.

Methods involving these LC modes will be briefly discussed below.

5.1 Gel Permeation Chromatography and Normal-phase Liquid Chromatography

For the determination of apolar pesticides with accumulating properties in fat, e.g. organochlorine pesticides, the first step is the isolation of the fat from the fatty
matrix. Usually this is done by extraction with an organic solvent yielding an extract in which the fat has to be separated from the analytes. As regards vegetable, human and animal fat, cleanup will be focused on the separation between pesticides (low-molecular-weight compounds) and triglyceride-esters (high-molecular-weight compounds).

Two powerful LC-based fully automated approaches are available using either GPC or NPLC silica cleanup to perform the separation between the fatty compounds and the pesticides. GPC is applied most frequently since its separation, based on molecular mass, results in the widest scope concerning both matrices and analytes. The availability nowadays of HPGPC columns packed with small size particles (7–10 μm) providing small elution volumes of analytes, typically 100–300 μL, allows the coupling of GPC to GC allowing automated procedures. The advantage/disadvantage of the NPLC silica cleanup approach is that the high separation power of analytical column packed with 5 μm silica favors selective cleanup but counteracts the range in polarity of analytes. Productive methods have been developed for monitoring of organochlorine pesticides in milk and various types of fatty matrices and 1,1-dichloro-2,2-bis(4-chlorophenyl)ethane (DDE) and polychlorinated biphenyls (PCBs) in extracts of adipose tissues employing NPLC off-line or on-line, respectively. For the determination of the more polar organophosphorus pesticides in mussels the separation between analytes and fat was successfully carried with NPLC by collecting the analyte in a fat-free fraction using different mixtures of hexane–ethyl acetate.

### 5.2 Solid-phase Extraction Combined On-line with Gas Chromatography

The coupling of SPE to GC provides fully automated procedures for the determination of pesticides in environmental water samples. Small volumes of sample, typically 1–5 mL, are sufficient to obtain the required sensitivity. PCs (10 × 2 mm ID) packed with 15–25 μm PLRP-S copolymer have been used for the on-line determination of nitrogen- and phosphorus-containing pesticides in water at the low nanogram per litre level. This PC material shows favorable properties for the required solvent-phase switch involving (i) adsorption of analytes during sampling, (ii) the removal of water by passing nitrogen and (iii) desorption of pesticides with an organic solvent, e.g. ethyl acetate.

An automated “off-line” SPE system (ASPEC) has been coupled to GC with electron capture detection (ECD) for the on-line analysis of pyrethroid insecticides in water. This approach combines extraction and cleanup by adding 30% of modifier (methanol) to the water sample prior to SPE on a 100 mg C18 cartridge and a washing step of 1 mL of 30% methanol in water. After drying with air, the cartridge is eluted with 1.5 mL of toluene. GC analysis with ECD and on-column introduction of 100 μL of the extract provided LODs in the range of 1–8 ng L⁻¹.

### 6 CONCLUSIONS AND TRENDS

LC has proven to be an efficient technique in PRA making it very complementary to GC for the determination of polar and/or thermolabile pesticides. LC methods cover samples from both the disciplines of public health and environmental protection and the column switching mode easily provides semi- or fully automated procedures including on-line cleanup and/or trace enrichment. Future developments in LC will be focused on the enhancement of sample throughput, robustness, scope of analytes, selectivity, sensitivity and, even more importantly, reduction of cost.

Providing high selectivity/sensitivity for the determination of pesticides with widely different (physicochemical) properties, RPLC combined with APIMS is a powerful and attractive technique, and increasing use in this field of analysis can be expected. Especially in studies on the identity and concentration of formed TPs, always more polar then the orginal pesticides, LC/MS will be a highly desirable technique.

Despite the high selectivity of MS or MS/MS combined use with column switching techniques, viz. SPE/LC or LC/LC, can be attractive in order to eliminate matrix-dependent quantification of analytes in the processing of uncleaned extracts.

In comparison to conventional LC, capillary LC offers a number of favorable features such as reduction of solvent consumption, improvement of sensitivity and interfacing to more selective and sensitive detectors. Because of the susceptibility of the technique to clogging/contamination problems caused by the excess of matrix interferences the use of capillary LC in PRA is still limited. Here, column switching appeared to be favorable to enhance sample load and cleanup as shown for the coupling of capillary LC to infrared spectrometry for the unambiguous identification/determination of medium polar pesticides in surface water at the 2–5 μg L⁻¹ level.

An interesting development in obtaining high selectivity is the on-line coupling of RPLC and high-performance thin-layer chromatography (HPTLC) in the normal phase mode. This two-dimensional low-cost separation system offers high peak capacity, an attractive feature in PRA.

1 Introduction

Can mass spectrometry (MS) do for high-performance liquid chromatography (HPLC) what it does for gas chromatography (GC)? This is probably the question that many analytical chemists, biochemists and pharmacologists asked themselves while arguing in front of their ultraviolet (UV) chromatograms. In fact, the use of an ultraviolet/visible (UV/VIS) spectrophotometric detector, which is the most widely used detector for liquid chromatography (LC), is restricted in sample selectivity by the sensitivity in a particular absorption band. Other detectors, such as fluorimetric or electrochemical, are even more limited and rarely employed. When compared with GC, for which a variety of excellent detectors are available, HPLC detectors cannot meet the demand.

MS is the most specific technique for the detection and identification of organic compounds. MS can provide not only molecular weight information but also a wealth of structural details that together give a unique fingerprint for each analyte. MS is the detector with by far the highest information output per unit sample weight. The dynamic combination of gas chromatography/mass spectrometry (GC/MS) has yielded the most specific and sensitive method for the characterization of the components of complex volatile mixtures.

Under this circumstance, the use of a mass spectrometer as an HPLC detector has been widely investigated. Since the majority of all known compounds are amenable to HPLC, the integration of HPLC and MS greatly extends the range of compound classes that can benefit from the particular characteristics of MS detection. With uninterrupted evolution over the last 25 years, it has produced amazing results for both chromatographers and mass spectrometrists to the point that HPLC/MS represents one of the most important tools in the characterization of all organic compounds. Unfortunately, while the evolution of the coupling of GC and MS has led to a single, relatively simple and inexpensive device, progress in HPLC/MS interfacing, far more challenging than that with

In this article, a detailed overview of the current high-performance liquid chromatography/mass spectrometry (HPLC/MS) instrumentation, suitable for the determination of a large number of pesticides, is reported. Particular emphasis is given to the role of the mass spectrometric apparatus involved in each interfacing technique with several types of information regarding the ionization processes, analyzer principles and system configurations. The article gives an up-to-date picture of the current instrumentation that is available and readers will find only brief references to some important historical approaches that are no longer in use.
2 INSTRUMENTAL PARAMETERS INVOLVED IN PESTICIDE ANALYSIS

A number of parameters are particularly useful to the analyst in selecting the most appropriate HPLC/MS system to identify and quantify the analytes, depending on the chemical properties and complexity of the sample. Far from being exhaustive, we feel that the criteria described below are particularly important for evaluating the alternatives to accomplish the needs when performing pesticide analysis.

2.1 Mass Range

The difference between the upper and the lower limits of the mass-to-charge ratio (m/z) is called mass range and defined according to Equation (1):

\[ \Delta m_{\text{range}} = m_{\text{upper limit}} - m_{\text{lower limit}} \]  

Depending on the mass analyzer, the mass ranges can span from 500 to 3000 for a quadrupole or an ion trap to no upper limits for a time-of-flight (TOF) mass analyzer. Since the molecular weight of most pesticides is <500, the higher cost of an extended mass range is not required.

2.2 Mass Resolution

Mass resolution is the capability of a mass analyzer to resolve one mass from the adjacent mass and is described by Equation (2):

\[ R_m = \frac{m}{\Delta m_{\text{resolution}}} \]  

where \( m \) is the measured mass and \( \Delta m_{\text{resolution}} \) is the difference between two adjacent mass peaks. A resolving power of 100–1000 (1000–2000) is typical of low-resolution analyzers such as quadrupoles and ion traps and implies unit resolution. This mode of operation is particularly convenient when using HPLC/MS, since possible interferences can be removed chromatographically. The advantage offered by electron ionization (EI) is that the acquired spectra can be compared with those in libraries for the fast identification of unknown compounds. This interesting feature is currently available only with a PB interface. TOF analyzers can operate at both low and high resolution. Sectors operate at high resolution for accurate mass measurements with a resolving power of 5000–10,000. This allows the separation of more than one analyte with the same nominal mass and it represents an unsurpassed tool for the determination of elemental composition. It is particularly important to determine the increasing presence of pesticides and their metabolites in the environment. The performance of a sector can be enhanced, providing additional specificity, when more than one analyzer is placed in series either in four sectors or a hybrid configuration. On the other hand, the cost and the operating skills required for such an instrument are elevated. Triple quadrupoles and ion traps allow mass spectrometry/mass spectrometry (MS/MS) configurations at a lower price with competitive sensitivity.
2.3 Spectral Characteristics

The characteristics of a mass spectrum can vary widely, depending on the ionization technique, interface and analyzer used. Highly informative, fragmentation spectra are needed in those applications where structural elucidation and identification are under investigation. Fragmentation spectra are obtained when electrons coming from a hot filament (EI) ionize the analyte molecules. The PB is the only interface that provides fragmentation spectra in single analyzer configuration on both quadrupole and sector analyzers. Collisions within the interface [source–collision-induced dissociation (CID)], available with ES, or tandem mass analyzers (MS/MS) can be used to obtain fragmentation spectra.

It has been demonstrated that even polar or ionic pesticides can be analyzed under EI conditions. In this case and when the molecular ion intensity is too low, alternative ionization techniques can provide simple spectra containing the molecular ion. This is the case with APCI, ES and TSP. CID can provide additional structural information.

2.4 Limits of Detection

When performing pesticide analysis, one should keep in mind their extremely low concentrations in the matrix and all the possible interferences. Selectivity can be achieved in any of different steps of the analysis, from sample preparation to the different alternatives of liquid chromatography/mass spectrometry (LC/MS) equipment. Instrument noise can originate either from the components of the system or from the chemical background and may severely complete with the very low signal of the analyte at ultratrace levels. APCI, ES and TSP allow the detection of most pesticides at the picogram level, whereas PB is less sensitive, with detection limits in the range of nanograms. Improving the detection limits depends not only on the interface and ionization technique chosen, but also on the analyzer and on the analyzer configuration in the case of MS/MS. With the latter, increasing the signal-to-noise ratio allows the detection of extremely low concentrations of substances.

2.5 Universality

When dealing with complex mixtures or real samples, it is very welcome to count on an instrument that can respond to all components, especially when unknown molecules need to be characterized. This is particularly true in pesticide analysis when metabolites or adducts need to be characterized. Universality is in this case a fundamental requirement to guarantee the complete identification and quantification of the sample components. Once again, one can play with the selectivity to restrict the field of interest. The polarity of the molecule plays a major role in choosing the ionization technique. EI is the universal ionization technique for nonpolar, polar nonionic and ionizable substances. The use of EI is limited to the PB, but this does not represent a limit in pesticide analysis since the molecular weight of most pesticides is far lower than 600 u. ES is preferable with ionic compounds and APCI and TSP produce a very good response with polar nonionic and ionizable compounds.

3 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY COUPLING TECHNIQUES

3.1 Introduction

In its infancy, HPLC/MS was considered as an adaptation of GC/MS towards thermolabile molecules carried by a liquid medium. In the mid-1970s, EI was like a flagship for MS. A reliable, reproducible, library-matchable EI spectrum was the key for a winning GC/MS technology, so its adaptation to a vaporizable eluate was considered a valid approach for the emerging LC/MS ‘hyphenation’. At that time, the extension of the analyzable mass range was limited and so was the mass range of the analytes convertible into the gas phase. The HPLC eluate was therefore forced into a classical EI ion source directly or through a mechanical adapter. The first case, called direct liquid introduction (DLI), was first developed by Baldwin and McLafferty and consisted in direct vaporization and ionization of a split HPLC column effluent. The reduced flow rate (10–50 µL min⁻¹) allowed normal MS operation but, because of the solvent vapor residues, imposed chemical ionization (CI) as the only ionization choice. Simplicity was good but the sensitivity was only acceptable and did not match the performance of GC. The mechanical alternative to DLI into a conventional EI/CI source was the moving belt interface. This innovative interface consisted of an auxiliary vacuum chamber through which a Kapton moving belt carried the column eluate and evaporated the solvents. The dry solutes were carried into the ion source, vaporized and ionized. After a cleaning process, the belt was ready for a new cycle. Solvents were removed completely and EI was achievable. Major drawbacks were related to the mechanical complexity of the interface, loss of chromatographic resolution and memory effects on the reused belt. Both interfaces were abandoned and were replaced by the much more efficient and reliable PB interface. The PB interface, first developed as monodisperse aerosol generator (MAGIC) LC/MS to underline the monodisperse aerosol mechanism through
which the liquid effluent is introduced into the ion source, is the best EI-based LC/MS interface currently in production.

LC/MS interfacing has also introduced a new concept: the integration between coupling mechanism and sample ionization in one combined process. This innovative approach opened the way to new ‘soft’ ionization techniques, namely TSP, fast atom bombardment (FAB), and atmospheric pressure ionization (API), which have revolutionized MS with their ability to ionize high-molecular-weight molecules and, in some cases, allowing the detection of picograms or less of material. These techniques, producing poor or no fragmentation of the analytes, with the absolute predominance of the molecular ion in the mass spectrum, have their best attribute in a higher sensitivity for several compounds. Differently from EI spectra, which reproduce what was in the original sample, API encumbers interpretation with artifacts that were not present in the sample (adducts, polymers, etc.). For instance, aldicarb only produces significant \([M + Na]^+\) without a molecular ion \([M + H]^+\), which could cause difficulty for a novice. In addition, there is no capability for commercial library identification of unknowns or ‘unsures’ in the hands of novices. The lack of typical EI information capability was partially compensated by a contemporary evolution of high-performance, coupled MS analyzers (MS\(^n\)) that, although complex and expensive, ensured a valid identification criterion for the target compounds. The family of soft ionization techniques, readily embraced by protein chemists for their high-mass capabilities, were slowly converted also to the detection of low-mass analytes at ultratrace concentrations. Only FAB ionization, which opened the way for the use of MS in biomedical applications, was rarely applied to samples of environmental concern.\(^{(5)}\)

In conclusion, whatever the interface principle being used, it must be subject to three conversion processes, always required when LC is coupled to MS:

1. An evaporation process is required to convert the analyte from a liquid phase to a rarefied gas phase.
2. A pressure-reduction process is required to convert the analyte, separated at atmospheric pressure, into high vacuum for mass analysis.
3. An ionization process is required to convert an often-neutral sample into detectable ions.

The occurrence of the three processes may vary in sequence in the various interfaces but they must be always present. On this basis, two groups can be highlighted: the API and TSP interfaces, in which the ionization step precedes the vacuum conversion, and the rest of the interfaces in which the ionization occurs at high vacuum.

Daring combinations of up-to-date ionization techniques and advanced analyzers keep the LC/MS market very unpredictable but arguably, API and PB (TSP having largely been superseded by APCI) are now well established to be considered as the foundations for future interface developments.\(^{(6)}\) Figure 1 illustrates the domain of each interface with respect to GC/MS.

### 3.2 Thermospray

The TSP interface (Figure 2), developed in 1980 by Vestal et al.,\(^{(7)}\) was one of the first attempts at LC/MS techniques using soft ionization. A TSP interface addresses two fundamental problems: it reduces the pressure of the residual HPLC solvents into the mass spectrometer and self-generates ions of the analyte. Both results are obtained by applying heat to the incoming HPLC eluate.

![Figure 1](https://example.com/figure1.png) Domains of application of LC/MS interfaces.

![Figure 2](https://example.com/figure2.png) Schematic diagram of TSP interface. (Reproduced from Blakely et al.,\(^{(7)}\) with permission from John Wiley & Sons Inc.)
The liquid effluent is forced into a heated capillary tubing that ends inside a heated desolvation chamber. The heat vaporizes the liquid while it travels through the interface and the majority of the solvent vapor is removed by an auxiliary vacuum pump placed at the end of the path. Only a small fraction of vapor is admitted into the mass spectrometer through a small orifice in the chamber, thus achieving the required pressure-reduction step. When properly controlled, the TSP interface is capable of accepting aqueous HPLC effluents at rates up to 2 mL min⁻¹.

Nonvolatile molecules are retained inside the aerosol droplets while they diminish in size during the vaporization process. An electrolyte, added to the HPLC mobile phase, produces an initial electrostatic field on the droplet surface and, in a way that resembles ES ionization, promotes the analyte ionization: the rapidly desolvating charged droplets increase the surface field while diminishing their size, until the point at which the charged analytes are ejected into the vapor stream. Ions are extracted from the desolvation chamber and accelerated toward the mass analyzer. Ammonium acetate can be added postcolumn and is capable of enhancing ionization of target analytes.

TSP produces molecular and adduct ions of the nonvolatile analyte with poor fragmentation. Molecules that are neutral in solution may produce [M + H]⁺ ions during the TSP process while adding postcolumn ionic additives to the HPLC mobile phase can generate negative ions (NIs). A filament, producing gas-phase electrons, can be added to the chamber, inducing CI reactions with the solvent used as the reagent gas.

TSP is limited by the use of aqueous mobile phases. Lack of structural information is not compensated by higher sensitivity, which is two orders of magnitude lower than in ES. TSP may produce more fragmentation than FAB but is not comparable to the superior identification capability of PB that shares the same applicability. TSP shows its best attribute for ionic and polar compounds with molecular weights <2000 u.

### 3.3 Electrospray

ES⁽⁸⁾ has revolutionized MS with its ability to ionize high-molecular-weight molecules and detect even femtogram levels of material. The ES LC/MS interface relies on the API technique for ion generation. Similarly to TSP, the ionization of the analytes takes place into fast evaporating liquid droplets but, instead of using an electrolyte and a high temperature, an electric potential is applied to the incoming HPLC effluent at atmospheric pressure (Figure 3).

The intrinsic simplicity of the ES design makes it a successful tool for LC/MS interfacing. A strong electric field (2–4 kV) is applied between a hollow needle, through which the HPLC effluent emerges, and a collector. The high field at the tip of the needle produces a cone-shaped liquid meniscus from which a spray of highly charged droplets is formed. During their travel from the needle to the collector, the droplets evaporate while diminishing their size, thus allowing the electric charge to concentrate at the droplet surface. At this point, a prerequisite for the final gas-phase ion generation is that the analyte exists as an ion in solution or could be easily ionized through a charge transfer when still in solution.⁽¹⁰⁾ If a species is present with more than one ionizable site, then ES will also produce more than one charge in the gas-phase ions. The benefit is evident with high-molecular-weight substances where the multiple charged ions, generated by ES, shrink the mass spectrum into the mass range of a typical mass analyzer. The charge concentration, observed during the droplet evaporation, weakens the natural solvent cohesion up to the point at which electrohydrodynamic disintegration into many smaller droplets occurs. This mechanism ends when the droplet size reaches the Rayleigh limit (the point at which repulsive forces overcome the cohesive forces of the solvent) and eventually it results in the expulsion of the ionized analyte into the gas phase. This ion evaporation process is believed to be the major mechanism for ionizing smaller molecules.⁽¹¹⁾

At atmospheric pressure, the solvated ions pass the collector and, following their momentum, travel toward the analyzer. A gas curtain (usually nitrogen at 1 Torr pressure), placed between the collector and the vacuum region, impacts the incoming ions quickly removing the last solvent molecules and generating low-internal-energy quasimolecular ions. In fact, the energy of those impacts, controlled by electric potential applied to the needle, can be a useful source of CID spectra of the analyte.⁽¹²⁾ The CID spectrum, generated in the ES region, is qualitatively similar to the spectrum recorded on a tandem MS instrument and can provide
the structural information necessary for the analyte confirmation (Figure 4).13 However, the ion pattern does not show the high reproducibility of that with typical EI. Unlike the analysis by tandem MS, where the ions are separated before CID, in a source CID the isolation of any analyte ion relies only on the LC separation. ES is also very susceptible to the chemistry of solutions and all the equilibria involved may affect the final sample result.

Conventional ES usually operates between 1 and 10 µL min\(^{-1}\). Pneumatically assisted aerosol generation [ionspray (IS)] allows the use of higher flow rates.

### 3.4 Atmospheric Pressure Chemical Ionization

ES ionization is best suited for high polar species or molecules with an acidic or basic site. An alternative for less polar molecules is APCI.14 APCI relies on an API interface as in ES, but produces the ions directly in the gas phase after the solvent and solute have been completely evaporated. In order to promote vaporization, the HPLC eluate, at a flow rate of 0.5–2 mL min\(^{-1}\), is converted into an aerosol and rapidly heated to 450–550 °C inside an ionization chamber. Ionization is accomplished with a source of electrons addressed on-axis with the heated spray. The electrons are usually supplied by a corona discharge source but a \(^{63}\)Ni emitter can also be used. A plasma of reagent ions is produced at atmospheric pressure in the ion source by EI of source gases and solvents. At this pressure the chance of interactions between reagent ions and analyte molecules is very high and protonated ions are normally generated. The mass range is limited compared with ES but the applicability of APCI is wider, spanning from ionizable to nonpolar compounds. ES and APCI can be configured on the same instrument, enhancing the problem-solving capabilities of both.

### 3.5 Particle Beam

The PB interface15 can be considered as the liquid-phase counterpart of a GC/MS interface. Its design is not new but, differently from other attempts, survived the tough competition with the emerging API techniques and now plays a key role in the solution of several problems. The PB can be considered as a ‘transport’ interface in which the majority of mobile phase solvents are removed and the analyte is transferred into the mass spectrometer for the final ionization. The breakthrough of the PB interface is represented by the conversion of the HPLC effluent into an aerosol of high-surface-area droplets and, after a rapid evaporation, into a beam of solute particles. Even though the development of PB took advantage of several detailed implementations involving different aspects of its functioning,16 it still relies on three key components (Figure 5): (1) aerosol generator, (2) desolvation chamber and (3) momentum separator.

The production of a fine spray can be accomplished by either a pneumatic or a thermal aerosol generator designed to accommodate mobile phase flow rates up to 0.5 mL min\(^{-1}\). A dispersion gas, usually helium, is driven coaxially to the liquid jet. A capillary-scale version of the interface enhances the overall performance at mobile phase flow rates of only a few microliters per minute.17 The atmospheric pressure desolvation of the aerosol droplets produces a mixture of dispersion gas, solvent vapors and solute particles, but only the last (the high-momentum fraction) reaches the ion source, the rest being...
removed in the momentum separator. This effective and simple interfacing approach relies on a classical EI/CI ion source and generates reproducible, library-matchable spectra for easy compound identification. This is ideal for those applications where structure information for small (<1000 u), HPLC-amenable molecules are needed. Even though picogram-level sensitivity is hardly achieved, PB plays a unique role in the world of HPLC/MS interfaces.

4 MASS ANALYZER ALTERNATIVES

4.1 Introduction

A mass analyzer represents the heart of a mass spectrometer. Choosing among different mass analyzers is necessarily the first move and should precede any other consideration when approaching MS. They all do basically the same job, some just do it better than others and at a different cost. Mass analyzers come in a variety of shapes and sizes but they all require three conditions without which ion detection would be impossible: (1) high vacuum, (2) charged analytes and (3) gas-phase ions.

Besides these common features, mass analyzers differ significantly. They all use a combination of electric or magnetic fields or both in order to separate the ions in space or time. Each analyzer may excel in mass resolution, extension of the mass range, detection sensitivity or scan speed. Some of them may include the possibility of generating MS/MS or MS\(^n\) \((n = 1, 2, 3, \ldots)\) spectra following a high- or low-energy CID event. All of them are suitable for coupling with chromatography but at a different cost and with different results. In conclusion, as highlighted in Table 1, where a comparison among the most common analyzers is reported, each one should balance advantages and limitations in order to suit better the LC/MS needs.

4.2 Quadrupole

A quadrupole mass analyzer, as its name implies, consists of a set of four parallel electrodes with either a circular or hyperbolic cross-section. The electrodes, placed at

the four angles of a square, are charged with two voltage components: a direct current (DC) and an alternating current (AC) oscillating in the radiofrequency (RF) range. Opposing sets of rods share the same voltage pattern but are charged with a different polarity (Figure 6). The electric field created in the space delimited by the four rods is called the quadrupole field. The quadrupole field shows some peculiar characteristics that can influence the path of a moving charged particle. When the quadrupole field is placed between the ion source and the detector, the stability of the ion trajectory is directly related to the RF/DC voltage ratio applied to the electrodes so that only a specific m/z value is allowed into the detector for a given voltage ratio. By ramping the electrode voltages, but keeping the RF/DC voltage ratio constant, a complete range of masses can be passed to the detector and the mass spectrum recorded. Therefore, the quadrupole analyzer is basically a mass filter whose mechanism can be explained by the superimposition of a high-pass mass filter and low-pass mass filter. The positively charged rods permit the transmission of all the ions above a critical m/z value while the negatively charged rods permit the transmission of those ions below a certain m/z value. The overlapped region created by the two filters forms a band-pass for a specific mass-to-charge ratio whose width can be varied by altering the RF/DC voltage ratio of the opposite sets of rods. Mass resolution is directly related to this bandwidth but it usually remains low (1000 at m/z 1000). The mass range is also limited, often being lower than 1000 u, but in some cases it can be extended up to 4000 u. This limit can be easily overcome when an ES LC/MS interface is in use.

A quadrupole analyzer is less costly than other analyzers and permitted the wide diffusion of MS detectors among the chromatographic community. Today, the quadrupole can be coupled to HPLC by the means of any available interface. Its typical sturdiness and reliability make it the optimum choice for high-throughput applications where dirty samples and high backgrounds may affect the quality of the results. It has evolved also as a tandem analyzer (MS/MS) in a configuration known as a triple quadrupole. The third quadrupole is an RF-only system and for its characteristics is used as collision region for CID experiments. Quadrupoles are also used in hybrid mass spectrometer configurations in which different analyzers are coupled together.

### 4.3 Ion Trap

The ion trap analyzer is very close in principle to a quadrupole analyzer in which the positively charged rods are bent and joined together to form a donut-shaped electrode (ring electrode) and the remaining set of rods are transformed in two hemispherical electrodes placed above and below the donut (end-caps). This configuration (Figure 7) is called a quadrupole ion trap. The similitude does not end here: in fact, as in the quadrupole analyzer, an RF oscillating voltage is applied to the ring electrode...
although, differently from a quadrupole, a DC potential is not required. The end-caps can be charged with a ground, DC or AC potential. While the quadrupole analyzer is basically a mass filter that temporarily traps the ions into a two-dimensional space only during their stable trajectory inside the quadrupole field, the ion trap analyzer forces all the ions together in three-dimensional space inside the trap until, depending on their \( m/z \) value, they are ejected towards the detector. The extraction of the ions from the trap is \( m/z \) specific and is obtained only when an RF potential is applied to the end-caps. A full mass spectrum of the analyte is recorded by ramping the ring electrode potential. As the ring electrode potential changes, the frequency of the ion stability also changes until the end-cap frequency matches the resonance frequency of an ion. All the ions sharing the same mass-to-charge ratio become excited into an expanding oscillating motion up to the point at which they are expelled from the trap. The mass resolution is comparable to that of a quadrupole analyzer and is obtained confining the ions with a given mass-to-charge ratio in similar spatial position inside the trap volume. A buffer gas such as helium, admitted into the trap at a pressure of \( 10^{-3} \) Torr, promotes this process by cooling the kinetic energy of the ions. This process reduces time dispersion when the ions are expelled for recording.

The trapping principle is highly efficient especially when compared with a quadrupole analyzer where all the ions, except those with a specific mass-to-charge ratio that reach the detector, are wasted. This may generate, in theory, very sensitive full spectra not far from the typical selected ion monitoring (SIM) performance. Unfortunately, the ion accumulation process cannot proceed indefinitely since the spatial focusing of the trap may promote space-charge disturbances among too close oscillating ions, with loss of resolution and errors in mass scale calibration. Thus, ion access to the trap is pulsed and an automatic gain controller (AGC) regulates their admission from an external ion source. It is noteworthy that samples that give good results in a quadrupole instrument may be too concentrated, by one or two orders of magnitude, for ion trap MS. In an ion trap analyzer, MS/MS experiments are spaced sequentially in time instead of space. The precursor ion is kept in place by applying an RF potential on the end-caps and selectively ejecting the remaining ion from the trap. A resonating frequency that corresponds to the isolated mass is then applied to the end-caps, causing the precursor ion to increase its oscillation. After numerous collisions with helium atoms, product ions are generated and recorded. Instead of recording all the fragment ions, a new precursor ion can be selected and with a new sequence of operations MS\(^n\) experiments can be performed.

4.4 Time-of-flight

The TOF mass analyzer is, in principle, very simple, being based on the fact that ion velocity is mass dependent. A ‘linear’ TOF consists of an ion source, a field-free flight tube and a detector. As soon as the ions are generated in the ion source they are accelerated along the flight tube by a burst of electric potential. For every pulse a group of ions will acquire the same kinetic energy and will start at the same time. Based on this fact, each mass entering the flight tube has a different velocity: the ions of lowest mass have the highest speed. The initial group of ions will separate as they proceed along the flight tube and arrive at the detector at different times. Hence, the arrival time is directly related to mass or, in this case, \( m/z \). In this configuration though, a TOF instrument shows a poor mass resolution (~1000 at \( m/z \) 1000). Two factors are responsible for this effect: variable ion formation time and different initial velocity. Both factors will cause ions, of the same mass, to have different arrival times at the detector. A common variation of TOF, which allows a consistent improvement of the mass resolution, incorporates an electrostatic mirror (reflectron) into the field-free region to compensate for energy differences at the start. This field reflects the ions in a position close to the ion source where they are detected. The fastest ions, with the same mass-to-charge ratio, penetrate deeply inside the reflectron field before being reflected. The longer path to the detector is covered in the same time as the slower ions, thus increasing mass resolution.

TOF has characteristics that are ideal for structural elucidation problems, namely high sensitivity in the scan mode and high scan speed. The last feature makes it a valid contender for high-speed GC/MS applications and a sensitive detector for full-scan acquisition. It is noteworthy that SIM acquisition, although possible, does not improve the analyte response, the relative signals being extracted when all the ions have already been collected. Recent technology developments have also added high resolution and high mass accuracy to the list of TOF capabilities and it often used as second analyzer in MS/MS instruments (Q-TOF, EB-TOF, etc.). Newer Q-TOF instruments are appearing with a resolution of 15 000.

4.5 Sector

A sector analyzer is usually referred to as a sequence of electrostatic and magnetic fields located along the ion path with the purpose of selecting a highly resolved isomass beam (same \( m/z \) value). Sector instruments have been always considered the reference for high-performance, high-resolution MS, but their cost and complexity have often confined MS into an elitist club.
In a sector instrument, the ions, accelerated from the ion source at a voltage of 4–8 kV, are deflected in a circular trajectory inside a strong, sector-shaped magnetic field (B) (Figure 8). The radius of the trajectory is \( m/z \) dependent, being created by the balance between the centripetal Lorenz force and the ion momentum, so that ions of various mass-to-charge ratios are separated in space and exit the sector at different positions. The ion detector is located at the end of a single ion beam whose value depends on either the magnetic field or the accelerating potential. These fields can be varied opportunistically for mass spectra recording. In this simple configuration, the mass resolution is heavily affected by the thermal energy dispersion at the moment of the ion formation. In order to increase the mass resolution power of the instrument, a second radial electrostatic sector (E) is added on the ion beam path before or after the magnetic sector, thus creating a variety of tandem configurations. In the electrostatic sector the energy dispersion of the ions is converted into a spatial dispersion of isomass ions at different velocities. Then, entering the magnetic field in different positions, the ions undergo compensating deflections with a final refocusing of the beam. Sector instruments separate ions simultaneously but, since only one beam is allowed to the detector, no more than one species can be collected at a time. A multichannel array detector allows simultaneous detection over a larger area, collecting several ions at the same time.

Sector MS is still the instrument of choice when high-resolution \( (R \leq 100000) \) mass spectra are required. MS/MS operations, either with a four-sector (EBEB, BEBE) or a hybrid configuration (EBQQ, BEQQ and BE-TOF), can take advantage of the high-resolution isolation of the precursor ion or the higher kinetic energy available for CID experiments.

**5 MULTIPLE MASS SPECTROMETRY DETECTION**

A sequence of mass spectral detection in a chain of fragmentation events originating from an analyte ion is called MS\( ^n \) \( (n = 1, 2, 3, \ldots) \), in order to highlight the number of stages of mass analysis involved in the process (Figure 9). MS\( ^n \) is a very general term and does not define any particular instrument configuration. Generally, any process leading to the detection of fragment ions originating outside the ion source can be included in this category. The simplest form of MS\( ^n \) detection is a sequence of two mass spectral stages (MS/MS). In this mode, the first stage of mass analysis (MS\(_1\)) is used to isolate a selected ion (precursor ion) into a collision region. The precursor ion is

</table>

excited, usually by interaction with a collision gas (CID), leading to the formation of fragment ions (product ions). Product ions are eventually mass resolved in a second stage of mass analysis (MS$_2$). The energy involved in the decomposition process influences the extent and quality of fragmentation. As a rule of thumb a higher collision energy, like those achieved when MS$_1$ is a sector analyzer, leads to greater decomposition of any analyte precursor ion and, ultimately, more structural information. Both sensitivity and specificity are greatly enhanced in the course of an MS/MS experiment. The coupling of multiple stages of mass analysis provides further structural information. In the selected reaction monitoring (SRM) mode, a number of selected product ions are continuously monitored while a precursor ion is admitted in the collision region by means of the first mass analysis stage. This mode of operation, which resembles the selected ion monitoring (SIM) mode in EI, yields the highest specificity for target analytes. The sharp increase in the signal-to-noise ratio after any stage of MS/MS operation may lower the analyte detection limit.

As shown in Table 2, MS analyzers can be arranged in different configurations to realize an MS/MS detector. Most of them can be optically coupled in a twin or hybrid configuration. In an ion trap mass spectrometer, where mass analysis stages are separated in time instead of space, the MS/MS process does not require an optically linked chain of analyzers and can, in theory, be repeated indefinitely. Double-focusing magnetic instruments, designed to focus or select ions based on both energy and momentum, can be used alone in a variety of different low-resolution scan modes to allow products of dissociation in the field-free region to be detected (energy scans, linked scans). A sort of CID, where the precursor ions can be only chromatographically resolved, is also available with the ES interface by means of the curtain gas region. MS$^n$ detection is of a crucial importance in HPLC/MS interfacing where most of the ionization techniques are ‘soft’ and considered insufficient for structural elucidation or analyte confirmation.

6 APPLICATION OF HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY IN PESTICIDE ANALYSIS

The heterogeneous group of chemicals known as pesticides can be found everywhere in the environment and their occurrence, even at low concentration, can be a serious threat to human health. In many cases capillary GC combined with the appropriate selective detectors or a mass spectrometer is employed. However, many pesticides currently in use are not amenable by GC owing to their polarity, thermolability and/or low volatility. In this case a separation in a liquid phase is more appropriate and HPLC/MS plays an important role.$^{18–21}$

6.1 Thermospray Interface

Several classes of pesticides have been analyzed with TSP, demonstrating the extensive use of this technique in environmental analysis. Even though it has been replaced by newer interfaces, its importance in the field is worthy of a detailed description. Although TSP ionization is known to be ‘soft’, producing a poor fragmentation, several techniques can be used to enhance the performance of this interface, increasing structural elucidation capabilities. These include the control of the vaporizer temperature, the use of MS/MS and the possibility of working in positive ion (PI) and NI modes.

The performance of TSP ionization over a broad range of pesticides has been investigated in a number of interesting studies. Bellar and Budde developed a broad-spectrum method for the determination of nonvolatile target compounds in aqueous samples.$^{22}$ Several classes...
of pesticides and herbicides, such as N-substituted amides, carbamates, sulfonylureas, triazines, phenylureas and others, were used to spike aqueous samples at 2–50 and 20–500 ppb levels for liquid–liquid and liquid–solid extraction. The TSP source was operated with the filament off, the discharge off and the repeller off and the detection was obtained in the PI mode. The LC mobile phase contained ammonium acetate alone or mixed with ammonium formate as ionizing reagent to perform volatile salt ionization (VSI) producing protonated molecular ions and other adduct \([M+H]^+\) and \([M+NH_4]^+\) ions. The detection limits obtained using liquid–liquid extraction ranged from 0.2 ppb for cyanazine to 18 ppb for linuron, while those obtained with liquid–solid extraction were higher owing to the small size and limited capacity of the cartridges used. Combining the information obtained from the LC separation and those from MS, this approach allowed the satisfactory identification of the target analytes.

Volmer et al. conducted an interesting study on the dependence of the temperature and salt concentration on the ion abundance in TSP mass spectra of several pesticides under CID conditions.\(^{(23)}\) In many instances, raising the vaporizer or the gas-phase temperature can promote further fragmentation. They demonstrated that, for some pesticide classes, fragmentation is mainly due to chemical reactions that occur in the gas or liquid phase rather than thermal decomposition. In another interesting paper, the same group demonstrated the applicability of TSP in the determination of 128 polar pesticides, with a wide range of structures and polarities, by combining the information obtained from the LC separation and those from MS, this approach allowed the satisfactory identification of the target analytes.

In a further development, Volmer et al. examined a series of nitrogen- and phosphorus-containing pesticides, polar pesticides and sulfonylureas, employing off-line and on-line solid-phase extraction (SPE) and LC/TSP/MS with time scheduled SIM.\(^{(25–28)}\) The precision, linearity and instrumental detection limits obtained allow the determination in full-scan mode of many analytes in the low nanograms per liter range, according to European Community Water Guidelines. In some cases, confirmation of the fragmentation pathways and further structural elucidation was obtained by comparison with APCI, ES, FAB, \(^{252}\)C Plasma desorption and CID spectra. Sulfonylurea herbicides and their degradation products in soil were also monitored in an early work by Shalaby et al.\(^{(29)}\) PI full-scan spectra, with the post-column addition of a solution of ammonium acetate, were generated, allowing the simultaneous determination of the compounds of interest at the 0.02 ppm level.

In another effort to determine multiresidue pesticides and their metabolites at trace levels, SPE either on Empore C\(_{18}\) extraction discs or on a conventional column packed with PRP-1 copolymer followed by LC/TSP with time-scheduled SIM was performed.\(^{(30)}\) The TSP/LC/MS system was operating in both PI and NI filament-on modes. Ammonium formate was added to the LC mobile phase. This approach allowed the detection of the selected compounds at concentrations of 0.02–0.4 \(\mu\)g L\(^{-1}\) in the water samples. Calibration plots, constructed using spiked estuarine water samples, show good linearity for 16 of the 34 pesticides considered. The same approach was used to detect the persistence of temephos and its metabolites in rice crop field waters\(^{(31)}\) and to determine chlorotriazine and its photolysis products in water.\(^{(32)}\)

Sixteen carbamate pesticides were used in a very interesting comparison, under standardized experimental conditions, among three different TSP interfaces and ion sources to evidence possible differences in ion formation and sensitivity of detection.\(^{(33)}\) Twelve of the investigated compounds showed no significant differences in their mass spectra, especially at low temperatures. Thermally labile molecules such as asulam, thiodicarb and thiofanox showed significant differences in the mass spectra, mainly due to thermally assisted hydrolysis of the parent compounds in the vaporizer probe, not necessarily reflecting differences in the ion source geometry.

### 6.2 Electrospray Interface

ES is one of the most widely used interfaces in pesticide analysis thanks to its high sensitivity and versatility. However, the use of this interface is limited to ionic and polar compounds. The introduction of ES has broadened the horizon in the analysis of thermolabile and polar compounds. The interface requires very low LC flow rates (<10 \(\mu\)L min\(^{-1}\)), meaning that the conventional LC column effluent must be split. Different solutions have been devised to overcome this inconvenience, one of them being the development of a pneumatically assisted ES interface (IS) that allows flow rates up to 2 mL min\(^{-1}\). This interface is particularly suitable for thermally labile analytes because it allows the nebulization of the column effluent at low temperature. The application of an extraction cone voltage adds the possibility of collisionally induced fragmentation, to help structural elucidation. This feature is common
to all API techniques. An interesting paper compared the performance of LC/TSP/MS and LC/IS/MS for the simultaneous determination of 10 carbamate pesticides in spiked tap water and river water and in two different types of spiked sediments which exhibit large differences in polarity.\(^{34}\) The use of the TSP interface for carbamate analysis had already been tested by the same group in a previous study in which they obtained satisfactory structural information, although sensitivity was not the point of force of this interface.\(^{35}\) The use of LC/IS/MS leads to detection limits between 10 and 50 pg in the SIM mode, whereas in TSP the detection limits for the same compounds are typically between 0.5 and 5 ng. Also, the repeatability in the ion signal intensities is better with the IS system. Coextracted compounds do not interfere with the analytes of interest in sediments down to the 50 \(\mu\)g kg\(^{-1}\) level (Figure 10a and b).

LC/IS/MS has been used in the determination of polar and/or thermally labile organophosphorus pesticides in water samples prior to SPE.\(^{36}\) This method permitted the identification also of some phthalates present as interferences, and the characterization of cis- and trans-mevinphos. The limits of detection were in the range 0.01–0.20 \(\mu\)gL\(^{-1}\) in the SIM mode.

Henion et al. reported the quantitative and qualitative determination of eight sulfonylurea herbicides in soil.\(^{37}\) The experiments were carried out with LC/IS/MS/MS in the SRM mode, providing high specificity and high sensitivity down to 0.05 ppb.

In a more recent paper, a multiresidue method for the determination of six pesticides belonging to three major pesticide classes, carbamates, triazines and ureas, in water, using an in IS LC/MS interface with a narrow-bore system, is described.\(^{38}\) In order to provide structural information, CID combined with mass analysis can be obtained by increasing the orifice voltage (OR) in front of the mass analyzer. In this work, two different ORs were used: a low voltage of 20 V gives peaks for the protonated molecule \([M + H]^+\) and the sodium adduct \([M + Na]^+\), and a high voltage of 60 V generates fragment ions from these precursor ions. This approach allows increased sensitivity without the need for a tandem analyzer instrument.

The spectra obtained at 60 V indicate that fragmentation had occurred by the expulsion from the protonated or cationized molecule of small, stable, neutral fragments. The results obtained are similar to those obtained with conventional MS/MS, the only drawback of this approach being that the chemical noise is not removed from the parent and fragment ion signals. This system allows detection limits lower than those required by the European

![Figure 10 Filament-on NI TSP mass spectra of 0.5 \(\mu\)g of propoxur, with 50:50 acetonitrile–water, (a) without additives and (b) with 50 mM ammonium acetate as the carrier stream. Community Drinking Water Directive for the compounds analyzed.

Several other classes of pesticides were detected at ultratrace level using on-line liquid–solid and SPE LC/IS. In the earlier study, thermally labile and polar organophosphorus pesticides in water were detected at the 0.1 µg L$^{-1}$ level combining various SPE methods with IS. Detection limits were 100 times higher than those obtained with TSP, with no thermal degradation, which allows the detection of thermally labile compounds. Extraction of particularly delicate compounds was accomplished using off-line SPE followed by the MS analysis. In the later study, several acidic pesticides such as benazolin, bentazone, 2,4-D, MCPA, MCPP, MCPB and 6- and 8-hydroxybentazone were detected in water samples at 0.01–0.03 µg L$^{-1}$. The mass spectrometer was operating in the NI mode for the acidic compounds and a voltage of 20 V was applied to the skimmer cone, and in the PI mode with a voltage of 30 V for the basic–neutral pesticides. An ion-pair agent was added to the mobile phase in order to achieve the separation of the acidic pesticides. The ion signal was affected by the nature of the ion-pair and its counterion and also by the nature of the pesticide itself. The limits of sensitivity for the acidic pesticides were estimated to be 2–6 ng L$^{-1}$ in drinking water and 8–25 ng L$^{-1}$ in surface water, and for the basic–neutral pesticides they ranged from 1 to 9 ng L$^{-1}$ from total ion current (TIC) and from 0.06 to 1.5 ng L$^{-1}$ from extracted ion current profiles. With little difference in the procedures, Di Corcia et al. demonstrated that this approach could be applied to a wide range of pesticides. The same LC/ES system was used for the analysis of carbamate insecticides at the picograms per gram level in fruits and vegetables, operating in the PI mode with a skimmer cone voltage of 30 V and time-scheduled SIM. Atrazine and its degradation products and sulfonylurea herbicides in water were also determined with the same instrumentation.

6.3 Particle Beam Interface

The PB interface, in particular in its capillary-scale version, is very competitive for the analysis of pesticides. Its major advantage relies on EI, which provides library-searchable, reproducible spectra of the analytes. Budde et al. were among the first workers to evaluate the suitability of the PB as a major component of a general purpose, broad-spectrum analytical method for the determination of pollutants. The results were encouraging in terms of response linearity, reproducibility and detection limits for a wide selection of polar compounds. A comparison between PB and TSP in the analysis of phenoxy acid herbicides was reported in another paper. TSP with NI detection showed better sensitivity, whereas the PB was more precise, particularly at the high concentration levels.

Phenoxy acid and ester herbicides were the target compounds in another method for their determination in soil and water. The PB was used for the confirmation of UV detection results. Detection limits ranging between 12 and 80 ng, corresponding to 4.8–32 ppb in water and 20–133 ppb in soil, were obtained with this method. EI showed the molecular and the phenoxy (base) ions of the selected compounds for unambiguous identification.

The advantages offered by a capillary-scale interface, developed by Cappiello et al., were found particularly convenient for the analysis of a large number of basic–neutral and acidic pesticides. The improved sensitivity, especially in reversed-phase conditions, lowers the overall detection limits, allowing the low parts per billion level determination of the target analytes in water. However, the results relative to the acidic pesticides are still affected by thermal degradation and an apparent loss of chromatographic resolution when eluted from the column. The difference is noticeable when comparing the TIC profiles for basic–neutral and acidic pesticides.

A breakthrough in the analysis of these compounds is represented by the use of Teflon® as the target vaporization surface. The validity of this approach is demonstrated by the analysis of 18 acidic pesticides with a Teflon®-modified ion source (Figure 11). The PI EI assay combines the advantages of a reduced mobile phase flow rate (1 µL min$^{-1}$) with a more efficient solute vaporization surface. Under these conditions, the original chromatographic profile is reproduced more accurately, with no signs of analyte adsorption or thermal decomposition. Instrument detection limits are improved significantly (0.6–5 ng), exceeding the parts per billion limit for the determination of the pesticides in water. Cappiello et al. developed an HPLC method in which ion interaction chromatography was coupled with a capillary-scale PB, allowing the simultaneous detection of basic–neutral and acidic pesticides. This
